Foreword

VOLUME 72 of the Transactions of The American Society of Mechanical Engineers contains the individual papers published during 1950 under the sponsorship of the Society's professional divisions and technical committees, including the contributions of the Applied Mechanics Division, issued originally in a quarterly known as *Journal of Applied Mechanics*, and the 1950 Society Records and Index. The technical papers and reports that make up this volume represent the Society's annual contribution to the permanent record of mechanical-engineering achievement. Most of these papers and reports were presented at meetings of the Society and its professional divisions and sections and were published in monthly issues, eight being distributed as the Transactions of The American Society of Mechanical Engineers and four as the *Journal of Applied Mechanics*. These indexes will be found at the end of this volume; an index to *Mechanical Engineering*, an index to the eight issues published as Transactions, and an index to the four issues published as the *Journal of Applied Mechanics*. Indexes to other ASME papers and publications will be found on page SR-59 at the end of this volume.

In view of the fact that the material of which this volume is composed was originally issued periodically as the Transactions, *Journal of Applied Mechanics*, and Society Records, three sets of page numbers will be found. Numbers without letter symbols are those of the eight issues of Transactions, and the *Journal of Applied Mechanics*, and those with letter symbol SR to the Society Records and Index section, which concludes the volume.

All sections of the Transactions are bound together at the end of the year for the convenience of libraries and of engineers who wish all of the papers in permanent form. Copies of the bound Transactions will be found in depositories located in selected engineering, university, and public libraries throughout the world. A complete list of these depositories will be found on pages SR-55 to SR-58 of the Society Records and Index. Copies of the Transactions have also been set aside for sale.

Solid-Type Journal Bearings in High-Speed Freight Service

By E. S. PEARCE,¹ R. J. SHOEMAKER,² AND I. E. COX³

This paper encompasses the operating conditions involved in the selection of the bearing equipment used in high-speed freight service. Consideration is given to the performance of the solid-type bearing, as well as the potentials of future development, and the superior adaptability of the solid-type bearing to the economics of railroad operation.

INTRODUCTION

THE term "high-speed freight" implies the shortening of elapsed time between terminals. This would require higher top speeds and more rapid acceleration.

The public has been led to picture freight equipment operating continuously at sustained speeds of 50, 60, 80, and 100 mph. To achieve this result, it would be necessary to have less gross tons per train; less resistance per train; or more power per train; or a combination of all three.

In the final analysis, high-speed freight must be obtained within the practical limits of cost and over-all economies of railroad operation. If high-speed freight is not to be restricted as to interchange, special equipment, and special movements, then all freight equipment must be equally adaptable to high-speed operation as and when the occasion arises.

For high-speed freight, bearings are involved in the elements of the following:

- Less resistance per train.
- Dependability and safety.
- Economy in first cost, maintenance, and weight.

There are listed, for freight-train service operation, 1,902,265 cars under railroad ownership, and 263,747 cars under private-line ownership.⁴ There are, therefore, in excess of 17,000,000 journals with companionate bearings in operation today. The investment in these journals and bearings, and the operation and maintenance of them are the common responsibility of all interchanging rolling-stock operators.

Six railroads have been selected as representing a cross section of certain operating conditions upon which an analysis of the over-all bearing problem for high-speed freight must be predicated. These six roads represent an operating ownership of 25 per cent of all freight equipment. Basic data are given in Table 1⁵ for the year 1947.

Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 48-A-128.

TABLE 1 AVERAGE NUMBER OF CARS IN EACH 100 CARS OPERATED BY EACH RESPECTIVE ROAD WHICH ARE OF OWNERSHIP OTHER THAN ITS OWN^a

Road	No. foreign cars per 100 cars operated
A	55.2
B	68.7
C	72.8
D	83.8
E	72.2
F	69.0

The basic elements of facility and economy of maintenance, repair, and replacement must be recognized as the first requirement of the bearing equipment.

Gross tons per train in high-speed freight will be made up in units of weights given in Table 2.⁵ It is the rolling resistance

TABLE 2 AVERAGE GROSS TONS PER LOADED CAR

Road	Gross tons per car		
	Average	Minimum	Maximum
A	58.4	57.0	59.1
B	55.6	54.9	57.8
C	55.5	54.1	56.3
D	52.8	52.2	54.0
E	53.7	52.7	54.2
F	69.7	69.0	70.4

of units of these weights that will determine train resistance. It is units of these weights that will determine the required bearing-load carrying capacity. It is under such bearing loads at the contemplated operating speeds, that bearing resistance in pounds per ton, in relation to total resistance, must be determined as a relative factor in high-speed freight.

Table 3⁵ gives the distance that the average car on line, which was in movement or subject to movement, traveled per day. It

TABLE 3 AVERAGE DISTANCE IN MILES PER DAY OF ALL CARS IN MOVEMENT OR SUBJECT TO MOVEMENT

Road	Distance per day, miles		
	Average	Minimum	Maximum
A	34.5	32.1	37.2
B	30.0	26.9	33.2
C	40.6	37.2	44.0
D	61.9	56.2	67.6
E	47.7	42.1	52.3
F	48.4	39.1	59.6

is only in movement that the function of the journal bearing assumes any relative and significant importance. It is in this distance that the functional advantages of the bearing are utilized and the investment justified.

Table 4 reflects the factor of dependability under the operating conditions as obtained in 1947.

TABLE 4 AVERAGE JOURNAL BEARINGS IN SERVICE PER DAY ON ALL CARS IN MOVEMENT OR SUBJECT TO MOVEMENT PER BEARING FAILURE

Road	Number of bearings for one failure		
	Yearly avg	Minimum	Maximum
A	37432	20288	113480
B	86948	48464	204984
C	32304	15992	97104
D	19424	9376	55304
E	33624	17576	69856
F	45560	20968	147072

A minimum average of one failure for 9376 bearings to a maximum of one failure for 204,984 bearings is equivalent to one failure for 526,931 bearing-miles as a minimum to 6,805,469 bearing-miles as a maximum. Since this reflects the actual performance of the solid unit-type bearing under existing operating conditions, this measure of dependability is an outstanding factor to consider.

UNIT SOLID-TYPE-BEARING TESTS

To determine the potential possibilities of the unit solid-type bearing under the more accelerated rate of operation of high-speed freight, it is necessary to turn to the laboratory test plant. Such tests are required since there are no road-test data available; nor is there ever likely to be, due to the inability to separate journal resistance from other elements which go to make up total car resistance. Likewise, extended operation under high speeds, effect of temperature, and other factors to give controlled conditions so that journal-bearing operation alone may be evaluated, are available only in the laboratory test plant.

In evaluating laboratory bearing-performance data, it must be recognized that laboratory operation is purposely "controlled accelerated service experience." Failure is the objective in order that the cause and effect may be determined and improvement devised and evaluated. A construction which may operate successfully on the railroad may fail under the adverse conditions in the test plant. These adverse test-plant factors are as follows:

- 1 Laboratory tests are conducted in still air, as against a high-velocity flow of air around journal-box contained parts in service.
- 2 The load on a journal bearing in a laboratory test is a maximum "dead" static load; whereas, in service, the load is "alive" and varying.
- 3 In a laboratory test there is no benefit of lateral motion of the axle in distribution of lubricant between the journal and the bearing; whereas, in actual service, the axle is constantly moving laterally, enhancing distribution of lubricant.
- 4 Speeds can be high and for extended periods of time not obtainable in practice. Rates of acceleration and deceleration, to and from high speeds, are attained that are not obtainable in practice.

Fig. 1 represents the data obtained with a $5\frac{1}{2}$ -in. \times 10-in. conventional solid-type journal-box assembly operated under the foregoing conditions, augmented by, subzero temperatures. The total bearing load was 16,375 lb, equivalent to a 70-ton car. The bearing, being nonfitted to the journal, had a crown area of only 22.5 sq in. The resulting unit loading was 735 psi. With a full or fitted bearing area of 45.7 sq in., the unit loading would have been reduced to 358 psi. The operation was one of constant speed at 50 mph for 66 hr. The run started in an atmosphere of +80 F, with temperature reducing, as the run progressed, to a minimum of -12 F. The operation was equivalent to a continuous run of 3300 miles. Ambient temperature, journal temperature, and journal resistance in pounds per ton are shown in Fig. 1.

To evaluate these results properly, some comparison should be made with total car resistance under like conditions of load, speed, and ambient temperature. This is true also for bearing resistance only of other types of bearings, such as those of multiple-unit design, of which type the roller bearing is a sample. However, such data apparently have not been developed.

As some measure of relative comparison, it is interesting to note that the distance of 3300 miles is 3 times the distance from New York to Chicago. The speed of 50 mph is 10 miles under the average speed of the 20th Century Limited.

Fig. 2 represents data obtained from tests using the same journal-box assembly and loading as used in the test covered in

FIG. 1 TEST DATA WITH $5\frac{1}{2}$ -IN. \times 10-IN. CONVENTIONAL SOLID-TYPE JOURNAL-BOX ASSEMBLY

Fig. 1, but operating in an atmosphere of -14 F to -10 F at speeds of 20, 60, 80, and 100 mph. On the speed-cycle curve are reflected acceleration, sustained speeds, deceleration, reversal of movement, ambient temperature, journal temperature, and resistance in pounds per ton.

SIGNIFICANCE OF JOURNAL RESISTANCE

It is in order to explore the potential significance of journal resistance in high-speed freight. For this purpose we have such basic data as shown in Figs. 1 and 2; and for available drawbar pull, motive power of the characteristics shown in Fig. 3.⁶ It is assumed that operation will take place on tangent level track with trains made up of 70-ton cars, at speeds of 50 and 80 mph.

Total car resistance for 70-ton cars at 80 mph is 10.5 lb per ton; at 50 mph, 6.7 lb per ton.⁷ Journal resistance only at 50 mph, Fig. 2, is 0.71 lb per ton. From Fig. 3, journal resistance after accelerating to 80 mph is 0.96 and 0.86 lb per ton. After running at 80 mph, it is 0.69 and 0.73 lb per ton. The average of these is 0.81 lb per ton. Drawbar pull of the S-1 locomotive at 50 mph is 36,000 lb and at 80 mph, 22,000 lb.

With bearing resistance entirely eliminated, the resistance of the 70-ton car at 50 mph is 5.99 lb per ton, and at 80 mph, 9.69 lb per ton on tangent level track. At 50 mph the available drawbar pull of the S-1 locomotive is equivalent to 86 cars of 70 tons each per train, and at 80 mph 32 cars of 70 tons each per train.

Speed has been increased 60 per cent to achieve high-speed freight at a sacrifice of 63.5 per cent in the number of cars per train for factors other than bearing resistance.

At 80 mph the bearing resistance for a train of 70-ton cars if entirely eliminated is the difference between a train of 30 cars as compared to 32 cars.

In freight service, under the prevailing conditions of railroad operation in the last 20 years, with the unit solid-type bearing, the average freight car has increased its average daily production as shown in Table 5.

Transportation service by the railroads, as required in this

country, makes necessary the highest degree of unrestricted movement of equipment over the railroad mileage of the continent regardless of territorial extent and ownership of any one railroad. Obviously, uniform and universal facility of maintenance is a basic necessity; hence there has developed a high degree of standardization and interchange of parts. This imposes severe

TABLE 5 TWENTY-YEAR INCREASE IN DAILY FREIGHT-CAR PRODUCTION

limitations on improvements in design, restricting changes to those not incompatible with maintaining standards.

It is recognized that improvements in design, materials, and practice relating to the unit solid-type-journal bearing-box assembly, can be made within the confines of the foregoing limitations of standardization.

THE JOURNAL BOX

There is general recognition of the necessity for a properly sealed and vented journal box to keep dirt, water, and other foreign matter out and to retain the lubricant in the journal box. Likewise, it is equally evident that lateral, in its ultimate reaction on lading and wear on mechanical parts, must be flexibly controlled and not rigidly opposed. These objectives are obtainable.

THE AXLE JOURNAL

Journals are finished by roller-burnishing, a practice which is scarcely conducive to a geometrically perfect surface. It requires considerable bearing-lining life and many miles of running to lap a rolled car journal to a satisfactory bearing surface. The permissible tolerances of journals, both diametrically and axially, are not only limiting factors in performance, but greatly

restrict the latitude in future bearing design and construction.

To illustrate, the $5\frac{1}{2}$ -in. \times 10-in. journal bearing is bored to $5\frac{9}{16}$ -in., but it is applied to a journal that will vary from a minimum of 5 in. to a maximum of $5\frac{1}{2}$ in.; and it is expected to perform equally well on either. Paradoxically, it does surprisingly well. Likewise, the length of the journal may vary as much as $\frac{11}{16}$ in. from maximum to minimum; and, at the same time, the bearing can vary in length $\frac{3}{8}$ in. due to wear, so that there is a total of $1\frac{1}{16}$ in. possible difference in the length of the bearing and length of the journal. Coupled with this is the further fact that these variations apply to only one journal on one end of the axle, whereas there may be a different combination of dimensional tolerances on the opposite end of the axle. A renewable journal sleeve will overcome these objections.

BEARINGS

The loads imposed on car journal bearings are well within the safe load limits of lead-base bearing lining. The low elastic modulus of bearing babbitt is the only reason that we have been able to operate successfully under the constant fluctuation of alignment, the widespread diametral tolerance, improper bearing and journal surfaces, and the great spread in both the quality and quantity of lubrication. It is the high plastic yield of lead-base lining which relieves the localized pressure caused by these conditions, thereby avoiding seizure and failure. This plastic condition of lining performs the important function of absorbing and removing abrasive materials from the journal surface.

Shock loads, caused by improper dimensional conditions of the wedge and bearing, are the cause of spread linings. This is in no sense a reason for condemning or changing the lining metal, as closer tolerances of the collateral journal-box parts will solve this problem. It is necessary to continue to use $\frac{1}{4}$ -in.-thick bearing linings, as this dimension is controlled by the journal diametral tolerance. This journal-bearing clearance has made necessary the design of the present bearing designated as the "no clearance type." The present journal collar fixes the bearing are at approximately 120 deg.

In considering improvements in design and materials of the present unit solid-type bearing per se, the low but widely fluctuating incidence of failure, shown in Table 4, presents an economic element for consideration. There is the question as to the relative improvement in performance that would accrue through proper maintenance practices, as compared to improved design and materials, although it is obvious that combination of both is the ultimate goal.

The economic value of relatively simple facilities of repair and maintenance of the solid-type bearing and journal-box assembly, wheels, and trucks must be recognized in considering improvements in design and materials. Likewise, changes in design and/or materials must be consistent with the economies of the present numerous sources of bearing supply with the added element of protection in time of national emergencies when railroad transportation is the backbone of defense.

The solid-type-bearing journal-box assembly, by virtue of its extreme simplicity, is victimized by unsubstantiated opinions and deprived of the benefits of facts. As an example, the derogatory misnomer, "friction bearing," established by advertising is now popularly accepted as descriptive of the standard AAR car journal bearing. The use of the term "friction type," applying to solid bearings, and the term "antifriction" to roller and ball bearings is erroneous and misleading, implying that friction is created in the operation of the solid type, and no friction in the operation of the roller and ball-bearing types. This is far from the true fact. Nonperformance in the proper functioning of any component parts of the journal-box assembly and truck manifests itself ultimately in a bearing failure. This results in promoting

the false idea that the bearing is deficient because it fails to overcome the detrimental influences introduced by the other component parts of the journal box and truck.

CONCLUSION

In its broadest aspect, the problems of bearing performance are not peculiar to the railroad industry alone. A co-ordinated, factual, aggressive, persistent, and effective approach to their economic solution has been far less evident in the railroad industry than in such other fields as aircraft, marine, automotive, and Diesel. This fact has been aptly described as an example of "What is everybody's business is nobody's business." Quoting Dr. Hersey:⁴ "The fact should not be overlooked, that in many applications where improvement has been reported as the result of the substitution of some novel type of bearing, equally good or better performance may be obtained from the simple oil-film bearing if properly designed and lubricated."

The Mechanical Division of the Association of American Railroads has facilities for the investigation of all elements of bearing performance. It now has under consideration an all-inclusive research and development program on this subject. Developments in design, materials, and practices, which are directed toward improvement in dependability, economy, and safety of the unit solid-type-bearing journal-box assembly, have been submitted to the AAR for investigation and evaluation.

APPENDIX A

The potential developments in the conventional solid-type-bearing journal-box assembly, without disturbing the standards of basic design and preserving the most essential facility of maintenance in unrestricted interchange, are shown by the composite illustration, Fig. 4.

The conventional journal box is cut away in section showing the axle journal, packing, bearing, and wedge, on the right or rear of the box, the oil-seal dust guard; and, on the left or front of the journal box, the water and dustproof lid. The small mirror in the front of the box is used to reflect the appearance of the end of the axle journal for purposes of illustration.

The dust guard and lid are to meet the requirement for a properly sealed journal box to keep dirt, water, and other foreign matter out and retain the lubricant in the journal box.

The axle journal, as shown, has had the conventional collar removed, and shows in place on the journal one form of sleeve. The use of the sleeve is to eliminate the use of journals varying

⁴ "Theory of Lubrication," by Mayo D. Hersey, John Wiley & Sons, Inc., New York, N. Y., 1936, p. 13.

FIG. 4 SOLID-TYPE-BEARING JOURNAL-BOX ASSEMBLY

$\frac{1}{2}$ in. in diam; and, as in the case of the illustration, a $5\frac{1}{2}$ -in. \times 10-in. journal, maintaining the diameter at $5\frac{1}{2}$ in. instead of a variation from 5 in. to $5\frac{1}{2}$ in. occasioned by the necessity for turning journals to repair surface conditions. The sleeve is $\frac{1}{8}$ -in. straight-wall tubing fitting over a $5\frac{1}{4}$ -in. journal with a very light shrink fit of 0.005 in. at 380 F. This provides a retaining force of 60,000 lb. Maintenance of axle-journal surface is accomplished by the renewal of the sleeve, no machining of the axle journal being necessary. To remove a damaged sleeve, simply split with a chisel and apply a new sleeve by heating to 380 F and rapidly slipping on the journal. The journal bearing is that described in a previous paper by E. S. Pearce.⁹

The journal-box wedge is the conventional wedge with a downwardly projecting ledge or lug welded to the existing wedge. This lug is to replace the function of the axle-journal collar to retain the journal bearing in place laterally. This eliminates the troublesome limitations introduced by the presence of the conventional journal collar, that is, service difficulties, as well as those pertaining to future bearing design.

The reflection of the end of the axle shows in the centering hole a plastic plug. This plug is made of a temperature-responsive material, whose liquid point and softening point are identical. The material can be made to respond within 2 deg F to any desired temperature. When the predetermined temperature is reached, the plug liquefies and by centrifugal force is spread over the end of the axle marking it a yellow color. The predetermined temperature is known as the "potential failure temperature." This temperature is an indication before a journal heating exists that attention should be given; and, if given, a road delay due to a journal heating will be avoided. The objective is to eliminate the personal equation in inspecting and servicing journal boxes by indicating positively those that need attention and, conversely, by the absence of the indication those that do not need attention.

Journal-box packing is of conventional material (waste and oil), applied, however, in the form of machine-made pads of oil-saturated waste. This insures uniform packing of boxes and prevents displacement of the packing in whole or in part from the normal position in contact with the bottom of the journal.

APPENDIX B

NATIONAL BEARING DIVISION—AMERICAN BRAKE SHOE COMPANY

The renewable axle sleeve and the compound bore bearing as hereinafter described, have been submitted to the Mechanical Division of the Association of American Railroads as two of our developments in design, material, and practice directed toward improvement in dependability, economy, and safety of the unit solid-type bearing and its assembly.

The Renewable Axle Sleeve. A renewable axle sleeve has been developed after several years of study and investigation, as illustrated in Figs. 5 and 6.

It consists of a rigid type of bushing made of high-carbon low-alloy steel, heat-treated to 480–520 Bhn, with ground journal and dust-guard-fit surfaces. This sleeve bushing is provided with a ground-finished taper bore $\frac{1}{4}$ in. to the foot, and is arranged to be locked in place by a nut screwed on the end of the axle.

Axle preparation for the use of this sleeve consists of turning either new or worn axles with a taper to fit the sleeve bore, and threading the end of the axle for the axle nut.

The renewable axle sleeve should be induction-heated or immersion-heated in oil to 200 F, and assembled on the axle, tightening the axle nut immediately so the sleeve will have a shrink fit in place.

⁹ "Locomotive and Car Journal Lubrication," by E. S. Pearce, Trans. ASME, vol. 58, 1936, pp. 37–45.

FIG. 5 CROSS SECTION OF RENEWABLE AXLE-SLEEVE ASSEMBLY

FIG. 6 PHANTOM VIEW OF RENEWABLE AXLE-SLEEVE ASSEMBLY

It can be removed readily by use of a hydraulic jack mounted in a stirrup with lugs to fit over the renewable axle sleeve collar so the jacking pressure can be applied against the end of the axle. The axle nut should be unscrewed only a turn or two so it will act as an arrester when the shrink fit is broken. A thin coating of white lead and oil swabbed on the axle before driving the heated sleeve in place will prevent galling of the sleeve on the axle.

The advantages claimed for the renewable bearing-axle sleeve are as follows:

- 1 The provision of a hardened and accurately ground journal, journal collar, and journal fillet will eliminate excessive wear and enable the use of full-size journals throughout axle life.
- 2 The use of the renewable axle sleeve will enable the continued use of worn axles that would otherwise have to be scrapped.
- 3 Axle life will be limited only by fatigue defects that are detected by magnafluxing.
- 4 By maintenance of proper journal size, the tendency of forming waste grabs will be reduced greatly because of the reduction in clearance between the bearing and the journal, adjacent to the contact area.
- 5 Both starting and running friction will be reduced due to improved fit between axle and journal, and by better and harder journal surface.
- 6 Bearing failures due to spread and distorted lining will be reduced since, with full-sized journal, component contained parts of the journal box will not be displaced from their intended position. This displacement of parts which occurs on undersize journal, also causes interruption to lubrication and packing down of waste away from the journal, two troubles that will be greatly reduced.

SIZE	A - DIA.	B - DIA.	C
5 x 9	5.004	5 1/8	1/32
5 1/2 x 10	5.504	5 7/8	1/32
6 x 11	6.004	6 1/2	1/32
6 1/2 x 12	6.504	6 3/4	1/32

FIG. 7 COMPOUND-BORE JOURNAL BEARING

FIG. 8 TIME-TEMPERATURE CURVE FOR AAR JOURNAL BEARING AS AFFECTED BY VARIATION BETWEEN JOURNAL DIAMETER AND BEARING BORE

Compound-Bore Journal Bearing. The compound-bore journal bearing has a secondary bore superimposed on the standard or primary bore, providing a precision fit 0.004 in. in diam over the nominal axle diameter approximately 2 in. wide, parallel to and in the center of the standard bore, as shown in Fig. 7.

The compound-bore bearing provides the equivalent to precision hand-scraped fit on a full-size axle. Where it is applied on undersized axles there is much less conformation of bearing required in initial operation. Comparative breaks in temperature characteristics are shown in Fig. 8.

The advantages claimed for the compound-bore car journal bearing are:

- 1 Possibility of waste grabs and lint burns is decreased during initial operation, which are invited by larger clearances adjacent to contact area between journal and a standard bore bearing.
- 2 Due to reduced conformation of bearing lining to journal surface, there is a reduction of pulling and cracking of the babbit lining.
- 3 Hot boxes are reduced by the reduction of both the severity and duration of high-temperature "break-in" period experienced initially on all bearings applied.
- 4 Lubrication is improved by insurance of a larger initial contact area under load, reducing the initial fluid-film pressure per unit of area. Frequently, initial fluid-film pressures com-

bined with high initial operating temperature, and relatively small initial contact areas causes oil film to fail, and in extreme cases fluid-film cannot even be established.

The compound-bore journal bearing is now in use by several leading railroads in both freight and passenger service.

The compound-bore journal bearing has been submitted to the AAR, requesting its approval as an alternate standard for interchange use and is on the test program. However, there will be no objection to its interchange use pending this approval since in no way does it conflict with specifications now in force, under which hand scraping of bearing bore is condoned and practiced.

APPENDIX C

MAGNUS METAL CORPORATION

Some of the improvements in designs and materials developed and recommended by the Magnus Metal Corporation in connection with the service of solid-type bearings and their assemblies in high-speed freight service, are herein described. These improved products have been developed as a result of many years research and they have a background of millions of miles of successful service in railroad operation.

Satco Bearing Metal. Satco bearing metal has been used very successfully for many years past as a lining for various types of railway bearings in place of lead and tin-base babbitts, antimonial lead, etc. This alloy was made an alternate for babbit metal in linings of freight-car bearings by the Association of American Railroads.¹⁰

Satco metal is a lead-base alloy composed of approximately 95-98 per cent lead with balance calcium and other hardeners. The composition of the alloy is varied according to the service in which the bearings are used. One of the mixtures used by the railroads as a general-purpose bearing metal contains approximately 97-98 per cent lead, with balance calcium and other hardeners.

Graphs showing the physical properties of Satco metal at normal and elevated temperatures, as compared with AAR lead-base babbit, tin-base babbit, and antimonial lead are shown in Figs. 9 and 10.

Satco metal has a melting point approximately 150 deg F higher than that of babbit metals with a correspondingly higher hardness at elevated temperatures. These are very important advantages as they are a measure of the heat resistance to spalling and melting of the bearing lining in service. This is particularly important in protecting the bearing against the effects of "waste grabs." Satco-lined bearings are said to function perfectly at temperatures where babbit-lined bearings fail by melting.

Satco can be bonded firmly to brass, bronze, steel, and aluminum, the bond strength between lining and brass being 20-40 per cent greater than that obtained with babbit-lined material. Consequently, bearings lined with Satco metal are more resistant to cracking and loosening of the lining and resist oil penetration to a much greater degree than with babbit-lined bearings.

Illustrations showing some of the various types of bearings lined with Satco metal used by the railroads for passenger cars and locomotives are shown in Figs. 11, 12, and 13.

"Twinplex" Satco-Lined Alarm Journal Bearings. The "Twinplex" Satco-lined alarm journal bearing shown in Fig. 11 is an AAR emergency-type bearing equipped with two brass tubes, each having a small orifice sealed with fusible metal which melts at 350 F. If the temperature of the bearing reaches that point, one of the tubes releases a distinctive and penetrating odor and the other a large volume of dense white smoke. The discharge continues until both tubes are empty, which requires

Fig. 9

Fig. 10

about 8 min. This device has had wide application for several years past on main-line high-speed passenger cars and locomotives of an important Eastern trunk line railroad. Experience has shown that the odor can be detected in any car in a passenger train, regardless of whether it is a tightly sealed, air-conditioned car or not. This odor is noticeable in the train for from 4 to 8 min.

"Magsafe" Satco-Lined Journal Bearing. The Magsafe Satco-lined journal bearing shown in Fig. 12 is a standard AAR type bearing equipped with a special device to prevent lint wipers and "waste grabs."

This device consists of two T-section brass comb strips one on either side of the crown of the bearing, positioned in longitudinal grooves milled in the brass. In running position, the comb strips drop down of their own weight and contact the journal at all times, regardless of whether the journal is new or turned down to the limit of wear, thus preventing lint and strands of waste from climbing the journal.

The comb strips are stopped off 1 in. from the hub end of the bearing to prevent end leakage of oil and to maintain full bearing contact at the hub end of the wheel.

The comb and slots are T-shaped to prevent combs from falling out of the bearing when being applied or removed from the jour-

Fig. 14 MAGNUS "R.B." SPRING-PAD JOURNAL LUBRICATOR

nal.* The comb strips distribute oil evenly along the journal, and they also provide oil storage in the bearing.

Magsafe Satco-lined journal bearings are being used as standard for main-line passenger-car equipment and regularly assigned Pullman cars on one of our important transcontinental railroads.

Magnus "R.B." Spring-Pad Lubricator. A recent Magnus development is the R.B. spring-pad journal lubricator shown in photograph in Fig. 14. This device is adapted to the standard round-bottom AAR type of box and is being used successfully in place of conventional packing in locomotive-tender, engine-truck, and trailer boxes.

The R.B. lubricator pad is inserted easily or removed without being necessary to jack up the box or remove the bearing and wedge. It is recommended for use in journal boxes of freight-car equipment in high-speed service in place of conventional packing, as a means of obtaining more efficient and dependable lubrication.

In addition to the designs and materials described, Magnus has also developed improved methods of casting, machining, and broaching of the standard AAR babbitt-lined freight-car bearing now being used by the railroads.

One new development is an improved method of casting the lining metal. From tests already made, the bond strength between lining and brass is increased from 20-40 per cent, as compared with the standard methods of casting heretofore used. This special process is still in the experimental stage, but it is being developed on a practical production basis.

Discussion

S. J. NEEDS.¹¹ The authors' comments on the use of the terms "friction bearing" when speaking of the oil-film type, and "antifriction" when referring to ball and roller bearings, are indeed timely. All bearings are fundamentally antifriction, since one of their functions is to operate with the least friction possible; but taken together, the foregoing terms do seem to imply that some

inherent friction miracle is to be found in ball and roller bearings. However, it is questionable whether many users of bearings are misled by this propaganda. Ball and roller bearings have been highly developed. They fill many important needs and have become vital parts of many mechanical structures. The methods by which they are produced form an outstanding part of our production achievements. It is unfortunate that they have been given a name that they cannot hope to live up to.

The company with which the writer is associated has been building thrust and journal bearings of the oil-film type for many years. Regarding load-carrying capacity, we generally think of the oil-film bearing as beginning where the ball and roller bearings leave off. This is seen in the many instances where we have replaced overloaded ball and roller bearings with oil-film bearings. As far as bearing life is concerned there is no room for comparison. A properly designed and lubricated oil-film bearing suffers no wear except at the moments of starting and stopping, hence will last practically forever. It is generally recognized, however, that ball and roller bearings, even though lubricated and cared for properly, are limited by an uncertain span of life.

There are instances where the two types are not in competition and fall into well-defined fields. For example it is almost certain that a majority of our automobiles would be stalled along the roads if sleeve bearings were substituted for roller bearings in the wheels without some complicated, and doubtless expensive, oiling system to insure their lubrication. The same crippled condition of the automobiles probably would also follow from substituting ball or roller bearings for oil-film bearings on motor crankshafts.

Both oil-film and ball and roller bearings have their inherent advantages. The latter have the definite advantage of holding a shaft in approximately the same relative position whether running or not. A pivoted-pad oil-film journal bearing will accomplish the same result, but that is not possible with a complete cylindrical bearing which must have running clearance. It may be that ball and roller types more properly could be called "anticlearance" bearings rather than antifriction bearings.

It is noteworthy that much theoretical treatment and many test results are to be found in the literature regarding friction in oil-film bearings. Similar data on ball and roller bearings are very few indeed and these fail to substantiate the term antifriction. In 1945 the writer published a paper,¹² in which an attempt was made to analyze friction in railway-car journal bearings of the oil-film type. Some tests were run later with roller bearings under similar conditions. These studies were sponsored by the Association of American Railroads. If the data on roller bearings were also published, they might throw some light on the relative frictions of the two types, and the quantitative value of the term antifriction could then be established for railway-car roller bearings.

AUTHORS' CLOSURE

To whatever extent or particular the operation of the conventional solid-type journal-box assembly per se may be factually deficient in meeting present-day requirements, it is evident that:

- 1 Economic improvement does not lie in replacement or substitution of the unit as a whole.
- 2 Improvement does lie in the proper evaluation of the nature, cause, and extent of presumed deficiencies.
- 3 With such factual evaluation available, the testing and selection of materials, practices, and designs of the elements of the journal-box assembly already developed will lead to the most dependable and economic operation.

The Development of a Design of Smokeless Stove for Bituminous Coal

By B. A. LANDRY¹ AND R. A. SHERMAN,² COLUMBUS, OHIO

This paper presents an account of an extended systematic investigation which resulted in the development of a method for burning bituminous coals in nonmechanical hand-fired heaters or stoves with substantially smokeless operation. The research was sponsored by Bituminous Coal Research, Inc., and a group of stove manufacturers. An experimental investigation of the three principles of combustion in fuel beds led to the adoption of the cross-feed principle. The design of a special grate and the research to prevent puffing, a difficulty often encountered with magazine heaters, are described. The principles of a calorimeter room in which the output of a space heater can be directly measured are presented. Data given show the thermal efficiency of a manufacturer's model of the heater, which had an output of 41,000 Btu per hr, to be 65 per cent.

THE United States leads the world in the number and proportion of residences that are heated from a central plant, and a high percentage of these use automatic firing of coal, oil, or gas. However, the Census of 1940 showed that 16,000,000, or about 47 per cent of the dwelling units of the country were being heated by some type of stove. Some 40 per cent of these dwellings use coal as a fuel. Because many dwellings use more than one stove, it can be estimated that there are probably about 8,000,000 coal-burning stoves in the United States today and several hundred thousand are sold each year. Estimates have been made that 25 to 30 million tons of coal are used annually in stoves.

Because these stoves operate on the simple surface-burning principle and because they are usually connected to low chimneys, the charge that stoves are important contributors to the smoke problem of cities where bituminous coal is used is probably not without some justification.

As a part of its program to develop improved equipment for the utilization of bituminous coal, Bituminous Coal Research, Inc. (BCR), the research agency of the bituminous-coal industry, initiated at Battelle late in 1940 a research project aimed at the development of stoves that would burn bituminous coal without the emission of objectionable smoke. In July, 1941, a group of manufacturers of stoves joined BCR in support of the program.

This paper presents an account of the steps that were followed in the investigation which has now culminated in the design of smokeless stoves which are in commercial production and are being sold and used. The design principles developed are applicable also to warm-air furnaces and residential boilers, and are now in process of being applied to these types of equipment.

GENERAL PRINCIPLES OF COMBUSTION OF BITUMINOUS COAL

As do all other natural solid fuels, and some processed ones, bituminous coals, when heated, release gaseous products composed of water vapor, hydrocarbons, hydrogen, and sometimes carbon monoxide, and carbon dioxide. The weight of these products is approximately directly related to the volatile-matter content of the coal. Following the process of distillation or devolatilization of the coal, there still remains an appreciable portion of the fixed carbon to burn. Hence, the complete burning of bituminous coals involves, usually in two steps, the burning of gases and the burning of solids.

When bituminous coal is burned in pulverized form, the single process of mixing air with coal particles is effective in carrying out the burning requirements of both gases and solids. However, when the coal is burned in fuel beds other than exceptionally thin overfeed beds, two distinct processes are needed to burn satisfactorily the two fuel forms. One, of course, simply involves passing air through the fuel bed to burn the coke; the other, requires (1) that air be mixed thoroughly with the gases, as they are released from the portion of the bed where devolatilization takes place, and (2) that temperatures be maintained high enough for completion of the combustion reactions. Failure to satisfy these two requirements results in the formation of smoke.

If no air is provided for mixing with the gases, and temperatures in the furnace are low, smoke consists mainly of a tar fog which is condensed hydrocarbons. If air is supplied but mixing is incomplete, and furnace temperatures are high enough to cause ignition, there will be regions of intense burning wherever oxygen is available, and other regions where, because of the absence of oxygen, the hydrocarbons simply will be heated by radiation to temperatures high enough to cause cracking, with formation of carbon or soot which will appear as smoke. Actually, both tar and soot may be emitted simultaneously with the gases from different parts of the furnace.

In mechanically fired industrial furnaces with good control of the air/fuel ratio, streams of gases rich in hydrocarbons may arise from certain portions of the fuel bed while other streams of gases, in which excess air is present, may arise from other portions. The mixing of these two streams may take place rapidly enough to avoid smoke formation if mixing arches are provided or if a large furnace volume gives time for mixing by diffusion. With smaller furnace volumes or higher rates of operation, which decrease time available for diffusion, smoke is of common occurrence unless overfire jets are used to establish turbulence where stratification otherwise would prevail. Even overfire jets, however, may not be completely effective if furnace volumes are too small or control of the air/fuel ratio is lost as a result of large intermittent firings.

Smoke emission from hand-fired heating equipment results from causes similar to those described, with considerable exaggeration of some of them, particularly in regard to the relatively large intermittent firings that are made, as is necessitated by the impracticality of frequent attention, and in regard to the low furnace temperatures usually maintained, which are unfavorable for ignition of the mixture but which are required to prevent overheating. The palliative of overfire-airjets is not available

for this type of equipment because furnace conditions would render them ineffective. Elimination of smoke from hand-fired heating equipment must depend primarily, therefore, on the selection and application of such combustion principles that will be effective purely as a result of design arrangements. The difficulties associated with following such a course have long been considered as affording little chance of success.

STAGES OF INVESTIGATION

The stages followed in the investigation were as follows:

- 1 A test survey of all those commercially available heaters, for which differences could be recognized in the principles used for combustion, in order not to overlook any promising feature of design. This period was also of value in the development of methods of test, including the use of a light-sensitive smoke meter, to insure reproducibility of results and the drawing of assured conclusions.

- 2 The selection of the cross-feed principle of burning, so disposed that the fuel moved downward from a magazine toward a horizontal grate above which cross-feed air and gases moved horizontally across the bed, and the addition of an arch of special construction to provide for the intimate mixing of secondary air with the gases escaping from the bed for complete combustion.

- 3 The introduction of air above the fuel fired in the magazine in order to alter the caking properties of the fuel and convert strongly caking coals to a free-burning form for gravity feeding to the "hearth" or cross-feed burning portion of the bed.

- 4 The development of special grates to insure horizontal flow of air above them, without danger of short-circuiting through the ashpit, and to provide a dumping arrangement to dispose of larger pieces of ash, especially laminated material.

- 5 The translation from the laboratory type of construction to a commercial design.

- 6 The development of a calorimeter room to measure directly the output of heaters and to make possible the evaluation of the various heat losses including the saving in fuel from smoke elimination.

RESULTS OF TEST SURVEY

Method of Test. The method of test used in making the survey, which remained essentially unchanged during the course of the investigation, consisted in placing the heater or stove on scales to observe the rate of weight loss during the burning, and providing flexible connections to the points where drafts were measured, temperatures taken by means of thermocouples, and gas samples obtained by means of water-cooled samplers. Imposed conditions to evaluate performance and to permit duplication of tests, to insure reproducibility of results, were either (1) to maintain constant flue-gas temperature, at some preassigned value, or (2) to maintain constant applied draft, again at some preassigned value. The first type of operation is valuable to show the frequency and type of attention required to maintain approximately constant output; the second type of operation serves to relate burning rate and output to applied draft to ascertain whether the burning process is under control. Both types of test were usually required for complete evaluation of the heaters.

Heaters Tested. Figs. 1 to 6, inclusive, show in diagrammatic form the burning principles of heaters on which tests were conducted during the survey stage preceding the development of the smokeless stove. In these diagrams the diagonally hatched areas represent solid fuel, whether freshly fired or at various degrees of devolatilization, except for Fig. 5 where the rectangular hatching represents freshly fired coal. Comments which follow refer to the performance of these heaters when burning bituminous coal.

Fig. 1 represents the conventional "surface-fired" heater with primary air admitted through the grates, and secondary air admitted either through the firing-door slots or through a "down-blast" pipe. This type of heater produces abundant smoke, because of poor mixing with secondary air, or low temperatures during devolatilization, or both; the period between attentions is short, but the average CO_2 is acceptable and draft requirements are well within the capacity of a small chimney.

FIG. 1 CONVENTIONAL SURFACE-FIRED STOVE WITH TWO ALTERNATE FORMS OF SECONDARY-AIR ADMISSION

FIG. 2 "MAGAZINE-TYPE" HEATER WITH DEEP FIRE POT

Fig. 2 represents a version of the so-called magazine-type heater having a deep fire pot, primary air passing through the grates and gases leaving the fuel bed at various heights through side channels or ducts, or at the top of the bed, the type of flow depending on the extent of caking in the fuel bed. The devolatilization of the charge is more rapid in this type of heater so that the smoking period, because of poor mixing with secondary air at low temperatures, is more intense although of relatively shorter duration than in the conventional heater, in view of the larger firing possible. The period between attentions is long, the

average CO_2 is acceptable, but the draft requirements are so low that the rate of burning may easily become excessive and control of heat output may be lost.

Fig. 3 represents a downdraft heater with part of the air supply passing through a rear slot to burn the gases at the outlet which is small in comparison with the size of heater. Because high temperatures are not maintained at the throat, owing to excessive air flow in comparison to the flow through the bed, smoke from this heater is abundant, rates of burning are low, and draft requirements high unless frequent poking is done to break the cake and prevent short-circuiting of primary air to the slot.

FIG. 3 DOWNDRAFT HEATER

FIG. 4 DUAL-SIDE HEATER

Fig. 4 represents a dual-side heater in which devolatilization takes place, because of lateral heating, in the fuel magazine; the volatile gases escape at the top and are allowed to mix with primary air which serves also as secondary air when passing through the edges of the bed. Because of poor mixing, abundant smoke is produced, rates of burning are low, with low CO_2 , unless frequent poking replenishes the fuel supply at the two sides, which also tend to burn at uneven rates.

Fig. 5 represents a divided heater with a half-circular lid which is pivoted on the partition. As the fuel in one half burns, the fuel in the other half devolatilizes by heat transfer, the gaseous products leaving through a hole in the partition to pass into the burning side; after refiring, the lid is rotated over the freshly fired side. Nearly smokeless operation can be obtained, with acceptable average CO_2 and low-draft requirements, if the heater is as small as a 14-in.-diam cylinder. With a further increase in diameter, heat transfer is not high enough to devolatilize all of the fresh fuel during the burning of the residual fuel, and with increase in diameter of heater, progressively more abundant smoke is produced after rotation of the lid.

Fig. 6 represents a type of cross-feed unit in which air is admitted at two levels, at the side (1) at the lower level, to burn the residual coke, and (2) at the upper level, to act as secondary air for mixing with the gases leaving the bed. Air is admitted also at the top of the magazine to alter the caking properties of the fuel in the magazine. Because of the unequal flow of the lower air, owing to its tendency to make a short curvature bend immediately after entering the heater, and thus escape contact with the fuel, the rate of burning can be maintained only by frequent poking to fill cavities formed, and smoke is produced in objectionable

FIG. 5 DIVIDED HEATER WITH PIVOTED LID

FIG. 6 SIDE-FEED HEATER

quantity because of poor mixing of the secondary air with the gases for the same reason. With frequent poking, average CO_2 is acceptable and the draft required is low.

Discussion of Results of Survey. Consideration of the results obtained during the survey led to a number of conclusions. One of these was that if the products of combustion, as they emerge from the fuel bed, contain smoke-forming constituents, the casual introduction of secondary air into the combustion space will not eliminate smoke. This results from the stratification of the gas and air streams, owing to their low velocities, at all rates of operation, in addition to the impossibility of attainment of temperatures high enough for ignition at the lower rates. Hence, a positive means of insuring mixing of gases with air in a region of high temperature, at all rates of burning, was indicated as a requisite for smoke elimination. This conclusion made it appear that a bed fired from above with air admitted through the grates was not a promising principle for the smokeless heater.

Another conclusion was that burning by means of admission of air at the top of the charge, as attempted in the heater shown in Fig. 3, could not be depended upon to prevent caking of bituminous coals rapidly enough to maintain air flow at the higher burning rates, and hence offered little promise.

By elimination, therefore, only the cross-feed principle remained as one upon which further investigation appeared to be warranted. None of the heaters tested in the survey could be considered as embodying true cross-feed burning; however, to the extent that the heater shown in Fig. 6 represented an attempt at cross-feed burning, to the same extent it could be concluded that this type of burning was not one which would give smokeless burning purely by virtue of the relative directions of flow of air and fuel.

BASIS FOR SELECTION OF CROSS-FEED PRINCIPLE FOR SMOKELESS HEATER

Although the cross-feed bed is used to advantage in so-called "underfeed-stoker" beds, yet, for this type of application, mechanical action is required to move the fuel from the retorts laterally across the tuyeres. Thus, if cross-feed burning were to be used in heaters, in the absence of mechanical means of feeding, the motion of the fuel relative to the air stream could only be so directed as to result in a downward flow under the action of gravity, the air movement being at right angles, or in a horizontal direction. This arrangement provided for the following distinct advantages:

- 1 Horizontal flow of the gaseous products of combustion across the bed would require the use of a vertical arch descending to a level adjacent to the grate to confine the bed while permitting the outflow of gases under the edge of the structure. Admission of secondary air in this region was indicated because the gases would be at their maximum temperature at all times to favor sustained ignition.

- 2 Generation of heat over the entire volume of hearth subject to cross-feed burning would favor transfer of heat through the upper boundary of the hearth for devolatilization of the fresh fuel fired in the magazine space above, and thus insure eventual minimum release of hydrocarbons during the cross-feed burning.

- 3 Constancy in the thickness of bed between the arch and the opposite wall would favor sustained combustion efficiency during the burning cycle.

In carrying out the development of a smokeless stove using the cross-feed principle of burning, there were two main stages, namely (1) stoves that required poking to bring the caked fuel down from the magazine into the hearth, and (2) stoves for which the necessity to poke was eliminated by providing oxidizing conditions during devolatilization to prevent caking.

FIRST STAGE IN DEVELOPMENT OF SMOKELESS STOVE

Fig. 7 is a diagrammatic view of the heater that was built to test in a preliminary way whether the advantages described would accrue from cross-feed burning. All of the primary air was admitted through louvers set in a wall opening opposite to the arch. Secondary air was admitted at the bottom of the passage under the arch through similar louvers, and a combustion chamber was provided on the other side of the arch to give time for the completion of the reactions. Results showed that, as compared with smoke emission from conventional heaters, much improvement had been obtained; however, observation showed that the stream of products of combustion, usually containing combustible

FIG. 7 PRELIMINARY CROSS-FEED HEATER

gases, passed closely under the bottom of the arch as they left the fuel bed and did not mix well with the stream of secondary air coming from below, and that the stratification thus set up did not disappear in the combustion chamber.

Fig. 8 shows the next design in which provision was made for the admission of secondary air through a flattened metal pipe, approximately 3 in. wide, set above a 7-in. refractory-lined duct serving as gas outlet. A 1-in. pipe vent was also provided to relieve the gas pressure that otherwise would build up at the top of the magazine owing to the formation of a hard and impervious layer of coke at the lower boundary of the fresh charge. The vent was so disposed as to make the gases mix with primary air before passage through the fuel bed.

Results were immediately so promising from the point of view of smoke elimination that there was no doubt that the proper method of introduction of secondary air had been provided to give complete mixing of air and gases as both streams moved along the bottom of the arch, that is, the top of the gas outlet or throat. The heat-exchanger section, attached to the outlet, no longer served as combustion chamber, but solely to dissipate heat. In the form sketched in Fig. 8, the heater could be placed in one room, adjacently to a wall, and the heat exchanger placed in the adjoining room, the connection outlet passing through a hole in the wall. Operation of the heater disclosed, however, that the rate of burning was definitely limited to low values under the maximum allowable draft; it was reasoned that the restricted outlet limited the flow of air to a small cross section of the bed in addition to offering rather high resistance to the flow of gases.

Fig. 9 represents the next important development. For this heater, a generally rectangular construction was adopted to

FIG. 8 SECOND VERSION OF THE SMOKELESS HEATER

FIG. 9 A THIRD VERSION OF THE SMOKELESS HEATER

provide a combustion-gas outlet as wide as the heater, and the heat exchanger was, so to speak, wrapped around the side and top of the heater for compactness. Secondary air, introduced through the ends of a refractory arch, was admitted above the gas passage, but the error was made of admitting the air through eight $\frac{1}{4}$ -in. holes spaced about 2 in. apart, whereas in the heater of Fig. 8 the secondary-air slot had extended continuously over the gas outlet. It was found that smoke was not completely eliminated, and it was verified that lateral stratification of streams of gases occurred, owing to lack of side mixing with air. An investigation was carried out whereby the individual holes were first replaced by four 4-in. divided slots having 1-in. closed spacing between them, and then by a continuous slot extending over the entire length of arch.

Table 1 summarizes average results obtained from four successive tests under each of the conditions listed. The advantage of replacing individual holes by a continuous slot, to prevent lateral stratification, is shown by the decrease obtained in recorded durations of smoke, indicated by the inclusive minutes above each of the conventional Ringelmann numbers. The average percentage of carbon dioxide obtained in these tests was also of interest in showing that, by standards of low-duty, hand-fired heating equipment, acceptable and rather constant combustion efficiency was being obtained with decrease in smoke.

In this connection, tests made with the four 4-in-slot arrangement had shown a distinct relation between the area of opening

increase of secondary air, both CO₂ and smoke decreased, but the reduction in smoke obtained with a CO₂ content as low as 9.2 per cent was not so large as that obtained by replacing the partial slots by a continuous slot, in further view of the fact that an average CO₂ of 10 per cent was obtained with the latter arrangement.

Discussion of Results of First Stage of Development. Although the evolution described in the design of the cross-feed heater properly could be considered to have solved the problems of smoke emission and of compactness of design, yet there remained the serious difficulty that the heater required poking to bring devolatilized fuel into the hearth. To minimize the labor of poking, successive heaters had been made smaller, with a firing door at the top, to permit more advantageous use of the poker in breaking the hard coke layer formed above the hearth section. Such small heaters had the disadvantage of a short interval between firings, of approximately 4 hr, as shown in Tables 1 and 2, and could not be construed as magazine heaters. This was confirmed in field trials of some twenty units of a jacketed heater based upon the heater shown in Fig. 9, for which the principal complaint was precisely the difficulty of poking. Hence, it was indicated that means had to be found to prevent caking in the magazine if a smokeless heater with true magazine feed was to be developed to give users the very tangible advantage of a long period between refirings, at rating, in addition to smokeless operation. This was the objective of the second stage.

SECOND STAGE IN THE DEVELOPMENT OF THE SMOKELESS STOVE

One of the simplest ways to prevent the caking of bituminous coal is to provide oxidizing conditions around pieces, as tar exudes from them while the coal is being heated. Little air is required to prevent caking in this manner when the rate of heating is low but the reverse is true at higher rates. The application of this principle to the smokeless stove appeared promising enough that

trials were made in a deep-magazine heater built for this purpose. As soon as confirmation had been obtained that caking could be prevented, a number of units were built for field tests.

Fig. 10 is a diagrammatic cross section of this second field-test unit which embodied a means of admission of magazine air, under controlled conditions, for self-feeding. The air was admitted through an external duct and entered near the top of the firing space above the magazine charge. Flow of this air through the fresh charge of caking fuel induced upward travel of ignition of the tarry substances, against the flow of air. Meanwhile, cross-feed burning, in the hearth, maintained heat output and provided the heat source from which the upward travel of ignition could start; thus the time was provided that is required to convert the caking coal to the free-burning stage to permit its

Fig. 10 SECOND FIELD-TEST MODEL OF SMOKELESS HEATER

descent into the hearth. This combination of principles was found to correct, in the manner described, for the operating deficiencies of the heater shown in Fig. 3, which depended entirely on downdraft burning to sustain the burning rate. Because of air admission to the magazine, the vent formerly used to lead fumes from the magazine to the point of entry of cross-feed air was no longer required and was not provided in the heater shown in Fig. 10, and in other heaters subsequently built.

Occurrence and Cure of Puffing. At this stage of the development, laboratory and field experience showed that, as a result of the admission of air to the magazine, "puffing" was introduced during operation, particularly following an adjustment in the rate of air supply. The puffing was normally inaudible but manifested itself by the emission of visible smoke puffs at one or more of the various air inlets to the heater, the smoke having the characteristic odor of incompletely burned gases from bituminous coal. This occurrence led to a rather long investigation to obtain a cure; the fact that puffs might appear at any of the air openings made it difficult to understand their exact cause.

Final conclusions reached were that puffing could occur as a result of two types of actions, namely, (1) formation of an ignitable mixture within the fuel-bed voids, in the vicinity of the secondary-air arch, when these voids were large enough to yield appreciable kinetic effects upon ignition of the mixture, and (2) formation of an ignitable mixture of combustible gases and air in the firing space above the magazine charge, followed by ignition of the

mixture, as a result of the upward travel of ignition to the top of the charge.

Fig. 11 shows the general design of three heaters used for the experimental work on which the first of these conclusions was based. In these heaters the magazine air was introduced within the charge rather than near the top of the firing space as in Fig. 10. The three heaters were similar in every respect, except that the dimension corresponding to the distance from the refractory arch to the opposite wall was only 11.75 in., as in the heater shown in Fig. 10, for the first heater; for the second heater, this dimension was 14.75 in. as in the heater shown in Fig. 11; and in the third heater this dimension was 18.25 in. When burning the weakly caking Illinois or Indiana coals in these heaters, under steady conditions, no puffing was observed. When burning the strongly caking Pittsburgh coal, however, puffs were observed, under steady operation, with the first of these heaters, but not with the other two having the longer dimensions from arch to wall.

The explanation for this behavior was that the residual-coke pieces formed with the more strongly caking coal were much larger than those formed with the weakly caking coals; hence the void spaces between pieces were also correspondingly larger, and appreciable kinetic effects could be developed, in the vicinity

Fig. 11 SMOKELESS HEATER WITH ADMISSION OF MAGAZINE AIR BELOW TOP OF CHARGE OF COAL

of the arch, provided there was enough residual oxygen brought into the void spaces to mix with the combustible gases also entering into them in their flow downward from the fresh fuel in the magazine. Since combustion efficiency would increase, with increase in the hearth dimension described, and also with decrease in size of coke pieces, it was apparent that only in the heater with the shortest hearth dimension were the two conditions both fulfilled, when burning a caking coal, of large voids and of enough residual oxygen to give an explosive mixture. This was confirmed by a flue-gas analysis which gave averages of 9.3 and 9.4 per cent CO_2 , over an 8-hr period, for the two larger heaters, but only 6.7 per cent CO_2 for the smallest when burning Pittsburgh coal without smoke formation. The net result was that freedom from puffing from this cause required that the arch-to-wall dimension be at least 14 in., with little gain in combustion efficiency from any further increase in this dimension.

The second process mentioned, in which a mixture of combustible gases and air could form in the space above the magazine fuel is illustrated in Fig. 10 by the arrow, showing the tendency for gases to leave the top of the charge in opposition to the downward flow of air. That such a process existed was demonstrated by the arrangement shown in Fig. 11 whereby the air required to induce self-feeding of the coal was introduced within the charge, through a narrow slot as wide as the heater, at a level some 2 in. below the top of the charge. Because little or none of the air passed to the space above, no puffing was experienced with this arrangement under steady or variable operation. However, a layer of hard coke was formed above the level of the air entry, and this layer remained in place even after the free-burning fuel below had fed down, thus giving a deceptive appraisal of the quantity of fuel in the magazine. Raising the level of self-feeding air admission to the level of the top of a normal firing was successful in avoiding the formation of the coke arch, but reintroduced occasional puffing following partial closure of the cross-feed air inlet to reduce heat output.

Fig. 12 illustrates how the change in level of air admission was carried out and shows also the next change made which was to provide a sloping roof in the magazine to halve, approximately, the volume available for the mixture and reduce the kinetic effects, following ignition.

FIG. 12 SMOKELESS HEATER WITH SLOPING ROOF OF MAGAZINE

The final arrangement designed to make it practically impossible for any slight puff to manifest itself outside of the heater was to provide a common plenum duct covering both the magazine-air and the cross-feed air inlets, and extending enough downwardly so that the duct opening would be approximately at the grate level.

GRATES OF THE SMOKELESS STOVE

Throughout the development of the smokeless stove, a great deal of attention had to be devoted to the development of a grate design that would (1) insure no short-circuiting of air through the ashpit in order to maintain the flow of cross-feed air above the grate, and (2) provide a dumping element for disposal of unburned refuse.

Fig. 13 shows the design of the final type of grate developed. The close-fitting fingered portion is intended to offer enough re-

sistance to the flow of air to prevent short-circuiting while effectively serving to shake the bed and remove the fine ash released. Unburnable refuse is transferred by the motion of the grate into the troughlike end grate, under the vertical gas passage, for periodic removal by turning a crank attached to the trunnion support and thereby dumping the accumulation. The dump grate is counterbalanced to return automatically to a sealing position under the frame. A special re-entrant at the wall adja-

FIG. 13 PLAN AND SIDE VIEW OF SPECIAL GRATE FOR SMOKELESS STOVE

cent to the first rocking finger grate serves to prevent wedging of hard coke against this grate element.

CHARACTERISTICS OF PRESENT COMMERCIAL SMOKELESS HEATER

Fig. 14 shows in diagrammatic form the design of one of the present commercial smokeless stoves on which the plenum duct described earlier is visible. A feature of this design is the replacement by alloyed metal of the refractory portion of the arch, formerly on the fuel-bed side, to give longer life under existing

^a Smoke data include 8-hr burning test and 16-hr banking period.^b Smoke data include start of a new fire.

stresses. Table 3 summarizes typical test data obtained with this heater on a 24-hr firing cycle, 8 hr at rating and 16 under bank. The smoke-emission data are for 24 hr; those given in the first column include the start of a new fire, which by comparison even with the smoke normally emitted following a re-firing, as shown in the other columns, would not be considered excessive.

The user of the smokeless stove regulates the heat output by adjustment of the cross-feed air damper only, except when chimney draft is excessive, when adjustment by means of a turn damper in the flue, or a barometric damper, may also be required. The magazine-air damper and the secondary-air dampers are adjusted by the coal dealer as follows: The magazine-air damper is set at the wide-open position for strongly caking coals (all Appalachian coals), at the mid-open point for mildly caking coals (Midwestern coals), and at the closed position for anthracite, coke, or the free-burning subbituminous coals and lignite. The secondary-air damper is set at the full opening for high-volatile coals, at the mid-opening for low-volatile coals, and at the closed position for anthracite and coke. A double-screened coal within the size range 3 to 1 in. is best-suited to the heater; smaller sizes have been found to give caking difficulty and larger sizes may contain impurities difficult to discharge through the dump grate. Run-of-mine coal is not recommended.

CALORIMETER-ROOM TESTS

A not inconsiderable part of the investigation for the development of the smokeless stove had to do with the design and construction of a calorimeter room in which the heat output of heaters could be measured directly. Fig. 15 is a cutaway view of the structure that was built for this purpose. On a simple

FIG. 15 CUTAWAY VIEW OF CALORIMETER ROOM

stud-and-joint framework 12 ft \times 12 ft \times 8 ft, were attached sheets of 1/2-in. rigid fiber insulating board provided with differential thermocouples to indicate the average temperature difference between the inside and outside of the wall. Two blowers were mounted on the roof to force air in and withdraw air through constricted ducts for measurement of both (1) the quantity of air flow by means of Pitot tubes, and (2) the temperature of the air by means of thermocouple grids. A highly insulated floor was used. The room was calibrated by use of an electric heater, the unknown being the average thermal conductivity of the walls and ceiling which was obtained by subtracting from the known heat input the heat corresponding to the temperature rise of measured air flow and dividing by the indicated average temperature difference between the inside and outside wall and ceiling thermocouples.

Otherwise, the room was provided with all facilities for running burning tests of heaters from which heat losses in the dry flue gases, in the steam, and in the refuse could be determined directly. Knowledge of the heat input from the weight of coal burned and of the output as given by the room data thus made it possible to evaluate normally unaccountable heat losses due to tar and soot in the gases. By such tests it was shown that a conventional heater, such as shown in Fig. 1, gave a heat loss, due to smoke, of the order of 12 per cent of the heat input. By comparison, smokeless heater BCR-2 gave an unaccounted-for loss of less than 3 per cent.

Table 4 summarizes the heat-balance results from a typical test run in the calorimeter room on a 12-hr firing cycle with a commercial model of the BCR smokeless heater, using Illinois No. 6 coal. The rating output obtained of 41,000 Btu per hr with an applied draft of 0.05 in. of water and with firings every 12 hr, was also obtained with Island Creek and with Pittsburgh bed coals with this heater.

TABLE 4 SUMMARY HEAT-BALANCE RESULT, CALORIMETER ROOM TEST OF A COMMERCIAL MODEL OF THE BCR HEATER, 12-HR FIRING PERIOD

(Illinois No. 6 coal, size 2 in. \times 1 1/4 in.)		
Measured heat output, Btu per hr:		
Heat gained by room air.....		32350
Heat loss through wall.....		11140
Heat from flue pipe.....		2560
Rating output of heater (12-hr basis).....		40930
Heat balance		
	Btu/lb	Percent
Heat utilized (efficiency).....	7649	64.6
Losses:		
Steam.....	656	5.5
Dry flue gas.....	2539	21.4
CO.....	70	0.6
Ashpit.....	591	5.0
Unaccounted for.....	335	2.9
Calorific value of fuel.....	11,840	100.0

For the 5 ft of pipe in the calorimeter room, Table 4 shows that 2560 Btu per hr corresponding to a 4 per cent gain in efficiency was transferred to the room. In a residential installation, additional recovery of heat and gain in efficiency may be realized from the flue pipe and chimney. However, because this is so variable with different installations and is uncontrollable after the installation is made, the efficiencies are reported here, as in usual practice, only on the output of the heater, including the first 20 in. of the metal flue pipe.

Under average winter-load conditions, firing would be expected to be required about once in 18 to 24 hr, and banking periods as long as 72 hr, followed by good pickup, have been obtained.

Fig. 16 is an exterior view of a circulator-type commercial version of the BCR smokeless heater. Fig. 17 is an exterior view of a radiant-type commercial version, the performance of which is similar to that of the circulator type.

A smaller-size radiant unit has also been developed and is in

commercial production. Fig. 18 illustrates this heater which has a rated output of 25,000 Btu per hr, under a 12-hr firing period, at an applied draft of 0.040 in. of water. The indicated efficiency of this unit is 67 per cent when burning bituminous coal.

Patent applications have been filed in the United States and Great Britain and various claims allowed for the developments described in this paper. A Canadian patent has been issued.

ACKNOWLEDGMENTS

Acknowledgment is made of the significant contributions during the early stages of the work of Howard Limbacher, Henry Ostborg, and Robert Mattox; in the development of the calorimeter room, of the work of Paul Vyff; and of the contributions of Edward Erickson and John Tieman, all former or present research engineers at Battelle Memorial Institute.

Especial mention is made of the contributions of Elmer R. Kaiser, assistant director of research, and James R. Garvey, development engineer, Bituminous Coal Research, Inc., and of King Ehret, president, Oakland Foundry Company, Belleville, Ill., in the translation of laboratory design to finished commercial design.

Finally, thanks are due to H. J. Rose, vice-president and director of research, Bituminous Coal Research, Inc., to the Hand-Fired Heating Committee of the Technical Advisory Board of BCR, to other members of the Board, and to the members of the Stove Manufacturers Research Group, for their helpful suggestions and sustained interest and support during the long program.

Corrosion-Erosion of Boiler Feed Pumps and Regulating Valves at Marysville, Second Test Program

By J. M. DECKER,¹ H. A. WAGNER,² AND J. C. MARSH,³ DETROIT, MICH.

Corrosion-erosion tests at 320 and 385 F indicated that, at these temperatures, carbon steel is attacked to a lesser extent than at 250 F, whereas the reverse is true of the chromium-bearing steels. However, the rate of attack of the chromium steels is still only a fraction of that of carbon steels, so that use of the alloy steels for boiler-feed-pump parts is warranted at the higher temperatures also. Increasing the pH of the feedwater from 7.6 to 8.4 doubled the corrosion-erosion attack on carbon steel in the Marysville boiler feedwater at 250 F, as compared with previous tests at the lower pH. Of two bronzes tested, Navy M material appeared satisfactory at temperatures up to 320 F; a leaded bronze was unsatisfactory at all test temperatures in this program.

INTRODUCTION

IN a previous paper,⁴ the authors dealt with tests made at the Marysville plant of The Detroit Edison Company to determine the relative resistance of 18 different materials to the corrosion-erosion type of attack commonly experienced in boiler feed pumps and regulating valves. Feedwater at 250 F was used for these tests. Shortly after the paper was presented, plans were started for a 200-mw extension to the company's Trenton Channel plant. The plan adopted requires a cycle in which the feedwater temperature is 315 F at the boiler feed pumps. Initially, temperatures as high as 425 F were considered.

In order to obtain corrosion-erosion data for feedwater at the higher temperatures commonly found in newer power plants, a second test program was conducted at the Marysville plant. Temperatures of approximately 320 F and 385 F were chosen for the tests because they were within the range that was considered for the Trenton Channel and Connors Creek plant extensions, and because feedwater at those temperatures was available from the 7th and 4th stage heaters, respectively, of No. 7 turbogenerator. Since feedwater at 250 F from the boiler-feed-pump discharge of this same turbogenerator had been used in the earlier tests, the tests at higher temperatures should therefore evaluate the effect of the higher temperatures rather than some other variable.

Early in the test program it was noted that when the evaporator was taken from service, the pH of the feedwater increased from an average of about 7.3 to 8.3. Advantage was taken of

this situation to determine in one series of tests the influence of pH in this range on the corrosion-erosion resistance of cast carbon steel. Included in this series of tests was one specimen each of 1.25 per cent chromium, 0.5 per cent molybdenum steel and leaded bronze.

The purpose of this paper is to present (1) the results obtained in the second test program; and (2) a comparison of the information thus obtained with corresponding data from the original tests.

MATERIALS TESTED

Nine different materials were tested. The materials, with their chemical compositions and physical properties, are listed in Table I.

Six of the materials: Navy M (a bronze); 5 per cent Cr, 0.5 per cent Mo; 12 per cent Cr; 18 per cent Cr, 8 per cent Ni; Cr-Ni-Mo; and carbon steel, had been tested earlier at 250 F. With the exception of the carbon steel, which was used for control specimens, all of these materials had shown good corrosion-erosion resistance. They were selected, therefore, for testing at the higher temperatures. The other three materials were selected for the following reasons:

1 Lead bronze had been suggested by a pump manufacturer for wearing-ring material in boiler feed pumps for the Trenton Channel plant extension.

2 An alloy steel containing 1.25 per cent chromium, 0.5 per cent molybdenum is being used frequently for high-temperature steam lines, and, if found to have good corrosion-erosion resistance, could be used advantageously for boiler-feedwater service because it is readily available. Previous tests also had indicated that steels of low chromium content would be satisfactory.

3 Chromium plating was included because it might be useful for protecting existing cast-carbon-steel equipment from attack, if it possessed the corrosion-erosion resistance common to iron-chromium alloys.

Four specimens of cast carbon steel were used in the test to determine the effect of increased pH on the corrosion-erosion rate. Cast carbon steel was chosen because any effect which changing the pH might have would be more readily observed on cast carbon steel than on the materials possessing greater corrosion-erosion resistance. This test was made at 250 F, as more data for comparative purposes were available for that test temperature than for other temperatures.

Specimens of 1.25 per cent chromium, 0.5 per cent molybdenum steel and of leaded bronze were included with the four cast-carbon-steel specimens because no tests of these materials had been made previously at 250 F.

DESCRIPTION OF TEST

The test method and equipment used for determining the corrosion-erosion resistance of the metals have been described in detail in the earlier paper⁴ on this subject. Briefly it consists in exposing specimens of the material to be tested to the action of

high-velocity turbulent feedwater under conditions similar to those encountered in boiler feed pumps and regulating valves. The two parts of a test specimen with the mating faces upward are shown in Fig. 1.

During test, a weighed specimen is held in a corrosion-erosion tester as shown in Fig. 2. For 500 hr a differential pressure of 300 psi is maintained across the specimen. This pressure forces feedwater through the center hole in the bottom part of the specimen to impinge on the plain face of the top part, causing the flow of feedwater to change direction and leave the specimen at a velocity of about 200 fps through the slot openings in the lower part of the specimen.

At the end of the 500-hr period, the specimen is cleaned, reweighed, and the loss in weight calculated.

FIG. 1 TYPICAL CORROSION-EROSION TEST SPECIMEN BEFORE TEST

FIG. 2 SECTIONAL VIEW, CORROSION-EROSION TESTER

PROCEDURE AND RESULTS

At Marysville, six specimens were tested simultaneously. The six corrosion-erosion testers, pressure-measuring equipment, and pressure-regulating valves used are shown in Fig. 3.

Six series of 500-hr tests (tests No. 8 to 13, inclusive) were conducted in this program. As in previous tests, continuous records of pH, specific conductance, and dissolved oxygen concentration, were made with recording instruments, and were supplemented by spot tests made with indicating instruments to check the accuracy of the recorded values.

* Loss corresponding to 447-hour test.

** Loss corresponding to 439-hour test.

In Table 2 the specimens are identified and averages of pressure differential, temperature, pH, specific conductance, and dissolved oxygen concentration, and specimen weight losses are given for each test. Weight losses are shown graphically in Figs. 5 and 6, along with data obtained in earlier tests at 250 F.

In Fig. 5 the weight losses obtained at 250, 320, and 385 F for

each material are grouped together to show readily the effect of temperature on the corrosion-erosion rate of the various metals tested.

The weight losses obtained for cast carbon steel at 250 F are plotted in Fig. 6 to show the effect of the pH on the corrosion-erosion rate.

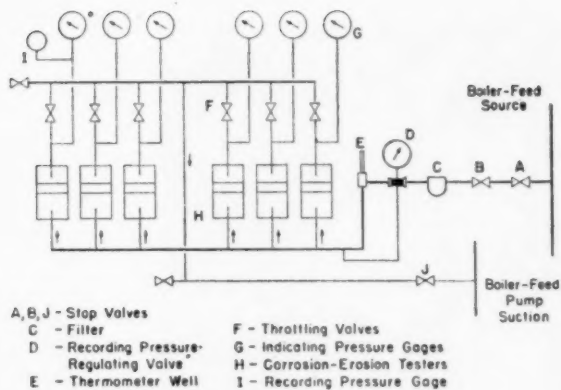

FIG. 4 SCHEMATIC DIAGRAM, CORROSION-EROSION TEST SETUP

FIG. 5 RESULTS OF 500-Hr CORROSION-EROSION TESTS OF CAST-METAL SPECIMENS AT VARIOUS TEMPERATURES (Pressure differential 300 psi.)

FIG. 6 RESULTS OF 500-Hr CORROSION-EROSION TESTS OF CAST-CARBON-STEEL SPECIMENS AT VARIOUS pH VALUES (Temperature 250 F, pressure differential 300 psi.)

DISCUSSION OF RESULTS

In general, test results indicate that cast carbon steel is more resistant to corrosion-erosion attack at high temperatures than at low (See Table 2 and Fig. 5). At 388 F, for example, the loss in weight (0.1978 g) is less than $1/10$ that of the average (2.2582 g) of six specimens at 250 F. An exception to this generalization was observed, however. At 318 F, Specimen 18A (test No. 9) was attacked so extensively that the 300-psi differential across the specimen could not be maintained after 447 hr of test. A careful analysis of test and water conditions revealed no variations that would account for the accelerated attack. Specimen 18C, which was made from the same bar, lost much less weight under similar conditions. Microscopic examination of the metal structure of the two specimens revealed no significant differences that would account for the variation in weight losses. There may have been some slight variations in specimen dimensions or surface finish, although it is difficult on this basis to account for the great difference in attack.

The indication that cast carbon steel has higher corrosion-erosion resistance at 385 F than at 250 F is substantiated to some extent by actual experience at Marysville. Recently a check valve at the discharge of No. 7 boiler feed pump, where the feed-water temperature is 250 F, was found to be badly damaged. An identical valve located in the same line at the discharge of the 4th-stage heater, where the temperature is 385 F, however, showed little attack after the same number of service hours.

Inasmuch as water is more highly ionized at 320 F and 385 F than at 250 F (see Fig. 7), it would seem likely that metals would be more rapidly attacked at the higher temperatures. In the case of cast carbon steel, however, it seems that a more tenacious oxide coating forms on the surface of the metal at the high temperatures than at the low ones, and actually causes a reduction in rate of attack.

FIG. 7 CHANGE OF HYDROGEN-ION CONCENTRATION WITH TEMPERATURE IN PURE WATER

(From "Properties of Ordinary Water Substance," by N. E. Dorsey, Reinhold Publishing Corporation, New York, N. Y., 1940, Table 182, page 378.)

During the series of tests that composed this study, it was observed that the color of the coating on the specimens depended on the temperature at which they were tested. At 320 and 385 F the coatings were black, indicating them to be magnetic iron oxide, and at 250 F they were red, indicating ferric oxide. The black coatings were more tenaciously bonded to the specimens and were more difficult to remove than the red coatings.

In all cases the chromium-bearing steels were much more corrosion-erosion resistant than the carbon steel. As would be expected, the 18 per cent chromium-8 per cent nickel had the highest resistance. At 250 F the corrosion-erosion resistances of the chromium-bearing steels were roughly proportional to their chromium contents. At the higher temperatures, the relative

advantage of the high-chromium alloys was greatly reduced. For example, at 385 F the corrosion-erosion resistances of the Cr-Ni-Mo steel containing 0.79 per cent chromium, and of the 1.25 per cent chromium, 0.5 per cent molybdenum steel were about equal to that of 5 per cent and 12 per cent chromium steels.⁶

The test results indicate that Navy M bronze should be satisfactory for service in feed pumps operating at temperatures up to 320 F. Two of three tests indicated that the rate of attack would be too high at 385 F for satisfactory service, the rate being about 10 times that found at 250 F. The rate of attack in the third test at 385 F was abnormally low, so much so that it was disregarded in evaluating this metal.

Test results obtained for leaded bronze indicated that it is not well suited for corrosion-erosion service at temperatures from 250 to 400 F. Experience with a coil-drains pump on an evaporator at the Trenton Channel plant corroborates these results. After operating for 6-months at approximately 400 F, the leaded-bronze wearing rings in the pump were badly damaged and had to be renewed, whereas other parts of the pump made of 12 per cent chromium steel were only slightly attacked.

Since even a small amount of chromium imparted a pronounced resistance to corrosion-erosion attack, it seemed that a thin chromium plate on the interior surface of carbon-steel pump casings might provide excellent protection for pumps already in service. It was determined that pumps could be plated at a reasonable cost. However, results of a test at 388 F of a chromium-plated (0.001-in. plate directly on steel⁶), cast carbon-steel specimen showed that the chromium plating was porous or cracked, which allowed the unprotected base metal to be attacked. The weight loss given for the specimen (see Table 2, test No. 12) is much too high as it includes part of the chromium plating which was stripped from the specimen during the cleaning treatment that preceded weighing. The view of the specimen, Fig. 8, shows that the chromium plating had broken down in spots and that the base metal had been attacked.

FIG. 8 TEST SPECIMEN NO. 1F; CHROMIUM-PLATED CAST CARBON STEEL AFTER 500-HR TEST AT 388 F

The results of the tests of cast carbon-steel specimens indicate that at 250 F the rate of corrosion-erosion-attack increases with pH between 7.6 and 8.4, the rate at 8.4 being about double that at 7.6 (see Fig. 6). This is contrary to what is usually expected. However, in a different type of corrosion-erosion test, conducted at Ohio State University on similar material, using distilled water at 122 F, the rate at pH 8 was about 10 times that at pH 6, (see Fig. 9). These data tend to substantiate results obtained at Marysville, although no direct comparison is justified because of differences in test conditions. However, it is indicated that in-

⁶ Chrome-plating directly on the steel instead of on an intermediate plate of copper and nickel was recommended by the plater as a superior wear-resistant coating.

FIG. 9 EFFECT OF pH ON CORROSION-EROSION OF STEEL
(W. A. Luce, Engineering Experiment Station News, Ohio State University vol. 19, no. 5, pages 29-32.)

creases in feedwater pH for the purpose of reducing corrosion-erosion attack should be made with caution.

The attack on the 1.25 per cent chromium, 0.5 per cent molybdenum-steel specimen at 250 F and pH 8.4 (test No. 13, Table 2) was about twice that measured in the other tests at higher temperature and lower pH (test Nos. 10 and 11, Table 2). No direct comparison to show the effect of pH on this alloy could be made, however, as no tests had been made at 250 F and the lower pH. Although it seems that the higher pH had little effect on the corrosion-erosion resistance of the leaded bronze, here again comparable data were not available.

It was noted at the end of the test at 250 F and pH 8.4 (test No. 13), that the specimens were exceptionally clean. There was very little, if any, of the red iron oxide which formed heavy coatings on the specimens during earlier tests at 250 F and lower pH. This seemed to indicate that the higher pH retarded the formation of protective oxide films on the specimens, thereby promoting metal wastage.

CONCLUSIONS

The rate of corrosion-erosion attack on carbon steel decreased with increase in temperature of Marysville feedwater, whereas the rate of attack increased for chromium-iron alloys. There is some indication that attack of the chromium alloys is greatest at some point between 250 and 385 F. At all temperatures at which tests were made, the chromium alloys were much more resistant to corrosion-erosion attack than cast carbon steel, and therefore they are considered to be satisfactory for service in boiler feed pumps and regulating valves up to 400 F in all Detroit Edison plants where the feedwater has similar characteristics.

The 1.25 per cent chromium, 0.5 per cent molybdenum steel and the Cr-Ni-Mo steel were not attacked to a significantly greater extent than the 5 and 12 per cent chromium steels at the higher temperatures. Because of greater weldability and lower cost, it appears that the low-chromium alloys might be used advantageously in feedwaters having similar or less corrosive characteristics.

Leaded bronze is not a good material for use at 250 to 400 F under conditions where corrosion-erosion attack can be expected. Navy M bronze is satisfactory at temperatures up to about 320 F.

Chromium plating as a means of protecting existing carbon-steel pump casings is not satisfactory.

As in the previous tests,⁴ the authors have not been able to deduce the underlying causes for corrosion-erosion attack, nor to determine which of the many variables is the most important. Increasing the pH of feedwater at Marysville from about 7.6 to 8.4, however, approximately doubled the rate at which cast carbon steel was attacked. This indicated that, for the Marysville feedwater, the lower pH is more desirable from the corrosion-erosion standpoint. While in some quarters higher pH values have been advocated as a panacea for all corrosion-erosion troubles, these results would seem to indicate that some caution should be exercised in increasing pH of feedwater indiscriminately.

Discussion

T. W. BIGGER.⁶ The Detroit Edison Company is to be warmly commended for making the investigation which is so ably reported in this and the original paper. The work has been carefully done and the information which is reported is usable and valuable to the industry.

Corrosion-erosion to an abnormal degree occurs only occasionally in a steam turbine, but is similar to that in feedwater pumps, in that it does not follow a set pattern as to the apparent conditions under which it does occur. Corrosion-erosion will be quite severe in a turbine in one plant, and an identical turbine in another with the same pressure and temperature conditions will be virtually free of damage. The erosion occurs principally on the low-carbon-steel parts, the high-chromium steels being but little affected by this type of attack.

Corrosion-erosion is not a serious problem in the superheat region of steam turbines, nor in the coldest stages at the exhaust end. However, it does occur in some machines in the so-called wet region, principally in the range where the steam contains up to about 5 per cent moisture. One turbine did not erode appreciably during the early months of operation when on base load, but corrosion-erosion became quite noticeable when the machine was changed to variable and intermittent operation. This can be construed as indicating that oxygen is a contributing factor.

Some time ago the writer's company studied the problem of determining the best method of making tests to solve the erosion problem. Moisture which is freshly formed within a turbine in a modern station is of a very high degree of purity, containing less impurities than the average distilled water. It was determined that the production of steam of sufficient purity in a laboratory would be extremely difficult and almost prohibitive in cost. It seemed that steam extracted from a turbine where erosion had occurred would be representative, and the Boston Edison Company kindly agreed to let us run the tests with steam extracted from such a turbine in its Mystic station.

About that time the original paper⁴ by the present authors was published. Since the arrangement of specimens which they used simulated closely the condition of a leak between a turbine diaphragm and a shell ledge, and it seemed desirable for purposes of comparison to use a specimen which had been agreed upon in the industry, our specimens are dimensionally identical with theirs. To make possible a clean job of heat insulation we mounted our specimens in a recess in a solid block of steel and covered them with a small flange containing a jackscrew for clamping the specimens together.

Saturated steam for testing is taken from the 14th-stage extraction line and fed to eight specimens at 25 to 28 psig through a well-drained header. The supply laterals are short and receive

steam from the top of the header. Several inches of each lateral are left bare to supply equal amounts of fresh moisture for the specimens. All inlet piping is stainless steel to minimize contamination. The exhaust goes to the main condenser where the pH of the condensate in the hot well is in the order of 6.5.

Tests of 1000 hr duration for a total of 16 specimens have been completed. Many of the specimens were of turbine materials commonly known as corrosion-resistant. They were run for purposes of comparison and of course stood up very well. A few specimens of cast low-carbon ferrous materials have been tried. From these essentially preliminary runs, we have been able to learn that 2 per cent chromium improves low-carbon cast steel for use under these conditions more than 4 to 1, a good check of the results reported in the paper under discussion. Cast iron was not benefited by the addition of up to 1.5 per cent nickel, but was improved nearly 50 per cent by the addition of 3 per cent nickel and 1 per cent silicon. Specimens of sprayed corrosion-resistant metals over cast iron are in test and in preparation.

A study is being made of the use of small amounts of alloying elements in carbon cast steel and cast iron with the object of producing useful low alloys at a reasonable cost. Samples of these alloys will be tested as rapidly as possible.

C. E. BRUNE.⁷ Evidence from operating results in several stations of the American Gas and Electric System seems to indicate that plain carbon steel is subjected to greater attack under higher temperature or lower pH. Attack was evident sooner and more severe in stations with feed pumps handling water over 400 F than in a station where pumping temperature was less than 400 F. At one station a set of pumps with feedwater pH of 7.5 experienced severe attack while another set with feedwater pH of 8.5 experienced none. Feedwater temperature for both sets was 450 F. When the low pH was brought up to 8.5, the attack ceased.

Another phenomenon was experienced whereby deposits of corrosion products on sides of impellers, causing increase of motor horsepower, apparently, were reduced when feedwater temperature was reduced, by removing from service the last heater. In some instances, at least part of the deposit resulted from corrosion within the pumps. In one station the deposits started when ammonia content went down in the river from which evaporated make-up originates, and feedwater pH fell from above 8 progressively to as low as 6. When ammonia content of river water and feedwater pH rose to normal values, the deposits apparently disappeared. There may be a question whether lowered temperature and increased pH lessened the formation of corrosion products or whether these changes influenced only the deposition of those products.

From test No. 13, the authors incline to the belief that higher pH retards the formation of protective oxide film. The writer wonders whether the slightly more complete deaeration in test No. 13, as compared with earlier tests reported in the previous paper,⁴ might not also have been a factor in retarding film formation.

While the authors consider the tests to justify use of the chromium alloys under test up to 400 F in deaerated feedwater, it is believed this limit can be raised, at least for some of those alloys, since no attack is evident on a 5.5 per cent chrome alloy in several stations on the A. G. & E. system after years of operation with deaerated feedwater at 450-460 F.

F. P. FAIRCHILD.⁸ This paper is a useful addition to the information presented by the authors in their first paper.⁴ Our

corrosion-erosion tests on steel specimens with varying pH values indicate just the opposite of the findings of this paper, as reported in discussion of the paper on the first test program. We found that a higher pH results in less corrosion-erosion attack at both 90 and 205 F water temperatures.

Recently we made some corrosion-erosion tests in an attempt to determine why high-pressure boiler-feed-pump parts of nickel cast steel had a longer service life at Essex Station than similar parts under similar conditions at Marion Station. Detectors made from diffusers of the Essex and Marion pumps were tested side by side under similar conditions in the Marion feedwater. Contrary to expectations, the detector made from the shorter-lived Marion pump had the smaller weight loss in 500 hr by 12 per cent. Thus difference in materials was eliminated as an answer to the problem.

Having eliminated material as a cause of longer life, we next investigated the effect of condenser leakage, because the Essex condensate comes from condensers with packed tubes whereas the Marion condenser tubes are rolled at both ends. A tank and a variable-stroke proportioning pump were arranged to permit the injection of fluid from the tank into the line carrying feedwater to one of the detectors. Thus we were able to make concurrent corrosion-erosion tests comparing normal with polluted feedwater, using detectors of like material (cold-rolled steel).

Three tests simulating condenser leakage were run; two at Essex (4th and 5th) and one at Marion (11th), as shown in Fig. 10 of this discussion. In all of these tests a solution of condenser cir-

FIG. 10 CORROSION-EROSION TESTS SHOWING EFFECT OF VARIOUS ADDITIONS TO TREATED FEEDWATER AT 200 F

culating water was injected into the line feeding one detector while normal feedwater flowed through the second detector. At Essex 0.7 ppm excess chlorides reduced the corrosion-erosion weight loss 21 per cent in 335 hr; and in the next run 2.2 ppm excess chlorides reduced the weight loss 37 per cent in 525 hr. At Marion the same test resulted in a reduction of weight loss of 47 per cent with 2 ppm excess chlorides in 500 hr.

Since the tank containing the injection water was an open tank, there was the possibility that oxygen in the water might be the cause of the unexpected results of pollution. Therefore, at Essex we repeated the test, polluting with undeaerated, pure condensate instead of raw water. The test shown as the 6th in Fig. 10, showed practically no effect of such pollution and very little dif-

ference in oxygen content of the two effluents. Another similar test (the 7th) was run in which air was bubbled through the condensate in order to increase the amount of oxygen in the injected condensate. In this case the corrosion-erosion of the polluted water was about 20 per cent greater than that of normal water. Thus oxygen was eliminated as a contributing factor.

The 12th test at Marion used a solution of chemically pure sodium chloride for pollution. In this case 2 ppm excess chlorides resulted in a reduction of corrosion-erosion weight loss of 21 per cent, about one half that resulting from the same excess chlorides with raw-water pollution.

In all of the foregoing tests, the degree of pollution was so small that there was no measurable difference between the pH of the normal and polluted water. This would seem to indicate that pH alone may not be the best criterion for controlling corrosion-erosion.

J. B. GODSHALL.⁹ The reported unexpected effects of raising the pH value and the temperature of the feedwater are of considerable academic interest. The major consideration, however, is the confirmation of the earlier conclusions regarding the vast superiority of the chromium-bearing steels over carbon steels.

It is particularly interesting to note that 12 per cent chromium has virtually no advantage over 5 per cent chromium, 0.5 per cent molybdenum stainless steel. Furthermore, the lower-chromium steel has certain advantages. For example, it is less susceptible to galling in pump service.

Still lower-chromium steels, such as the 1.25 per cent chromium, 0.5 per cent molybdenum steel, may be practical for the feedwater at Marysville. Caution will be required if this material is considered for use in the many central-station feedwaters that are more aggressive toward carbon steel than the Marysville water appears to be.

These considerations, plus the impossibility of maintaining absolute control of the many variables affecting feedwater quality from a corrosion standpoint, indicate that the pump materials always should be selected for their ability to withstand any of the conditions likely to be encountered. Then, nominal fluctuation of the pH value or conductivity, or even a change in the water temperature, will be of no practical importance from the standpoint of corrosion-erosion.

The failure of the chromium-plated specimen probably was not unexpected. This failure, however, should not eliminate chromium plating from consideration for all feed-pump applications. Shaft sleeves are relatively easy to plate, and have very good resistance to corrosion-erosion by the feedwater. In addition, they provide an extremely hard, excellent wearing surface.

A. L. PENNIMAN.¹⁰ The writer believes there is a strong probability that some of the factors assumed to have been insignificant in effect as to rate of metal loss were perhaps actually significant. This comment applies particularly to the first paragraph under "Discussion of Results."

Since the average velocity is quite high and is accompanied by a sharp change in the direction of water flow, it is considered likely that there will be considerable variation in filament velocities with respect to both time and cross section which can result in some cavitation effect with material acceleration of metal loss, depending upon characteristics of metal and water. Under such conditions, it is believed that minor surface variations could influence the results materially.

⁹ Metallurgist, Cameron Division, Ingersoll-Rand Company, Phillipsburg, N. J.

¹⁰ General Superintendent, Electrical Operations, Consolidated Gas, Electric Light & Power Company of Baltimore, Md. Fellow ASME.

While it is recognized that maintenance of a constant differential pressure tends to maintain the average velocity of flow constant and thereby hinder large progressive changes in rate of loss, it is believed that the static pressure is also of importance and should be recorded since it, as well as temperature, affects cavitation.

It is noted that to obtain water at different temperatures, water was taken from different parts of the cycle. It is our opinion that such waters may differ in effect because of factors other than temperature which may have been assumed to be insignificant, e.g., suspended matter, metal and gas content. A filter is shown in Fig. 4 of the paper which obviously was intended to remove suspended matter. It would be of interest to learn the type and construction of this filter, since our experience in filtering-out suspended matter from boiler feedwater has not been considered satisfactory.

While the use of an evaporator may have been a convenient means of varying the pH content of the water, it is our opinion that there were influences other than pH which were brought into the picture, e.g., evaporator carry-over of solids and gases. Also, can we consider that it makes no difference whether or not the alkaline source is ammonia, ferrous hydroxide, or a solid like caustic soda?

Reference is made to Mr. Luce's work at Ohio State University, with Fig. 9 given as an illustration. While the statement is made that distilled water was used, the oxygen content was not mentioned. Since it is extremely difficult to obtain zero content of oxygen and other oxidizing influences, it is recommended that some statement be made about this. It would also be of interest to know about how the pH variation was obtained, and how the hydraulic conditions varied. Was only one point obtained at pH 10 where a negligible loss is shown?

If Mr. Luce's work is used as a criterion, it would appear that quite a number of plants in attempting to improve conditions have made them worse in maintaining the pH in the range of 8 to 9. However, maintenance of a pH of 6 does not fit in well with the use of sodium sulphite to react with remanent oxygen in the feedwater.

AUTHORS' CLOSURE

The work being done by the General Electric Company at the Boston Edison Company's Mystic station should produce some worth-while information. Inasmuch as the tests are being made with wet steam instead of water, information on a new phase of metal wastage will be obtained. It is interesting that results of tests of 2 per cent chromium cast steel obtained at Mystic station are similar to those obtained at Marysville with water. Information to be obtained on corrosion-resistant metals sprayed over cast carbon steel also will be valuable.

Experiences of the American Gas and Electric Company do not agree with the test results obtained at Marysville. The authors cannot explain this discrepancy. There is a possibility, however, that at 450 F corrosion-erosion might be much more severe than at 388 F, the maximum temperature used in the tests at Marysville. Because of the many variables involved, comparison of experiences on pumps operating on different feedwaters can be most misleading.

At the Detroit Edison Company's Connors Creek Plant where the feedwater temperature is approximately 250 F, severe corrosion-erosion of the feed pumps occurred when the pH of the feedwater was about 8.5. In this case, at least, the relatively high pH apparently did not protect the pumps.

A few years ago the source of feedwater for the evaporators producing make-up for the Connors Creek plant was changed. The new supply is practically free from ammonia whereas the old supply contained an appreciable amount. This caused a lowering of the pH from about 8.5 to about 8. Unfortunately, a change to corrosion-resistant metals for pump repairs was made at about the same time. This made it impossible accurately to gage the effect of the pH change. Results indicate, however, that the rate of corrosion-erosion is no higher than it was previously, and perhaps lower.

The experience of the American Gas and Electric Company indicates that the chromium alloys will give satisfactory service at temperatures 60 to 70 deg F higher than the test temperatures used at Marysville. This is a valuable supplement to the data submitted by the authors.

Results of the test presented by Mr. Fairchild indicate that the salts present in feedwater may have a very profound effect on the rate of corrosion-erosion attack of metals. Previously it was commonly believed that pH and dissolved oxygen were the most important factors. If the concentration of sodium chloride in the tests at Marion and Essex stations influenced the test results so greatly, it is conceivable that the presence of other salts may also greatly influence corrosion-erosion rates. This opens a whole new field the investigation of which would provide valuable information, particularly where salt water is used for condenser cooling.

At Marysville the salt concentrations in the feedwater were very low and specific conductance records indicated that variations were small. Therefore it is doubtful if variations in concentrations from one test to another had much effect on the results obtained. Inasmuch as concentrations in many plants cannot be controlled closely, Mr. Godshall's statement that "... pump materials always should be selected for their ability to withstand any of the conditions likely to be encountered" is a good one.

The filter about which Mr. Penniman inquired was placed in the circuit to remove suspended iron oxide from the feedwater used in the test. The filter element is made of a spool wound with cotton cord. The authors have found these filters to be quite effective for this purpose in this and similar installations.

The authors have no data nor have they seen any which would prove or disprove that one alkali is better than another for increasing the pH for corrosion prevention. The authors are inclined to agree, however, that the means for varying this pH may be most important.

The static pressure at the inlet to the test specimens was maintained at 700 psi, and the outlet pressure was, correspondingly, 400 psi. The saturation pressure corresponding to 388 F is about 200 psi gage. It is the authors' opinion that cavitation was not a factor under these conditions, which is supported by the fact that the type of metal wastage resulting from cavitation was not found.

When referring to Mr. Luce's work at Ohio State University the authors neglected to state that it was done in aerated distilled water. The type of corrosion-erosion equipment used by Mr. Luce, and the conditions under which his tests were made were so different from the tests conducted by the authors that no valid comparison can be drawn between them. The authors merely wished to point out that some evidence exists tending to support the unexpected increase in corrosion-erosion attack secured on increasing the pH. These results were reported solely to indicate that changes in the pH should be made with caution.

The authors wish to express their appreciation to all those who submitted comments and discussion on the paper.

The Forces and Moments in the Leg During Level Walking

By B. BRESLER¹ AND J. P. FRANKEL²

The mechanism of normal level walking is presented in this paper in terms of the displacements of and the force systems at the leg joints. The data on four normal subjects were obtained from simultaneous recording of the positions of the leg in space and the floor reactions during level walking. The mass moments of inertia of the lower extremity were determined experimentally and the effects of gravity and inertia were included in the analysis. The forces and moments are presented in terms of the space components referred to a system of horizontal and vertical orthogonal axes.

INTRODUCTION

AS a locomotive mechanism the human body is extremely complex. In order to perform the various operations of locomotion such as walking, running, climbing slopes and stairs, man has been provided with an articulating system of levers (the arms, torso, and legs) connected by "superuniversal" joints (the shoulder, hip, knee, and ankle joints, for example). These levers are powered with a multitude of motor units (the muscle fibers) and operated by an elaborate network of controls (the nervous system).

The human mechanism is one that operates in three dimensions—further complicating its analysis. It is true that the main effects of locomotion are evidenced in a single plane (the plane of progression), but this should not lead one to neglect the effect of lateral displacement on the mechanics of locomotion. This omission has been made by some previous investigators in order to simplify the mechanical aspects of the problem, but does not seem to be justified by the results of this investigation.

Unlike the inanimate machines, one human body varies greatly from another in build (mass distribution), musculature (power supply), and mannerisms of motion (controlled by the nervous system). The effect of these variables on the displacement and forces involved in the locomotion process introduces an additional complication into the analysis of the experimental data.

Before attempting to correct any mechanical deficiencies in the human body, the surgeon, limb and brace maker, and physiotherapist must be well-acquainted with the mechanical functions of the affected parts of the body. The techniques and scope of orthopedic treatment and surgery, limb and brace fitting, and the like are seriously limited by the force and displacement characteristics normally involved in the damaged or missing members. Recognizing the need for a scientific analysis of the mechanical functions of the legs in walking, the Advisory Committee on Artificial Limbs of the National Research Council and the Veteran's

Administration sponsored a research program of fundamental studies of locomotion at the University of California at Berkeley.

In view of the range of variables involved in the mechanics of human locomotion, a complete analysis of the problem is not possible at this time. Various phases of this problem have already been reported (1),³ others are now under investigation at the University of California Artificial Limbs Research Project. The material presented herein is based upon the investigations carried out at the University of California, and will deal primarily with the force systems in and the displacements of the lower extremities during level walking of normal subjects.

HISTORICAL BACKGROUND

The present-day knowledge of the mechanism of locomotion is due to the contributions of many scientists. Only a few of these contributions will be mentioned here to introduce to the reader the state of present-day knowledge in this field.

In 1836, Wilhelm and Eduard Weber (2) presented a theory of walking and running based on measurements on cadavers and tests on living bodies. From studies of pendulum motions of the leg in both living and anatomical specimens the brothers Weber reached the conclusion that leg motion during the swinging phase of gait, that is, the time when the leg is off the ground, is a pure pendulum motion and does not depend upon muscular action. The Weber pendulum theory gave rise to much discussion by subsequent investigators and was later repudiated by Fischer and others. The Weber book contains also a great deal of information on other various aspects of gait, including a mathematical analysis of the data collected. In another publication Eduard Weber discusses some fundamental aspects of muscle physiology wherein the tension that a muscle can develop is compared to the shortening it undergoes. The importance of muscles as the prime movers of the articulating levers of the body focuses great attention on the work of Eduard Weber in this regard.

E. J. Marey, Professor at the College of France, reported in 1873, and on later dates (3, 4, 5, 6, 7) tests performed to determine the locus of the center of pressure on the sole of the foot and the vertical displacement of the body during walking. In addition, his computations of energy output during locomotion are worthy of mention in any bibliography however brief it may be. Marey's greatest contribution to the study of locomotion is no doubt his development of chronophotography. Successive exposures were made on the same photographic plate by means of a rotating disk in front of the camera. The subject was dressed entirely in black on which brilliant metal buttons and shining bands were attached to represent joints and bony segments. The subject, illuminated by the sun, was photographed as he walked in front of a black screen. This method is known as geometric photography, since the pictures obtained show points and lines only. Variations of this method have been used in practically all subsequent investigations, including that reported herein.

Otto Fischer, whose six volumes of research (8) were published from 1894 to 1904, is best-known for his studies on human gait.

³ Numbers in parentheses refer to the Bibliography at the end of the paper.

¹ Assistant Professor of Civil Engineering, University of California, Berkeley, Calif.

² Instructor in Engineering, University of California, Los Angeles, Calif.

Contributed by the Applied Mechanics Division, co-sponsored with Management and Aviation Divisions, and presented at the Annual Meeting, New York, N. Y., November 28–December 3, 1948, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 48–A-62.

These were based upon chronophotographic studies similar to that employed by Marey but with some improvements. Fischer, a mathematician, in co-operation with Braune, an anatomist, made detailed studies (9) of the kinetic properties of the different segments of the human body. To these men belongs the credit for the first rational scientific investigation of the problems in human locomotion; so detailed was their treatment of the subject that no later publication has superseded the works of Braune and Fischer and that of Fischer himself as the classical works on gait.

In Moscow, in 1935, was published a comprehensive volume (10) on research in the biodynamics of locomotion performed by N. A. Bernstein and his associates. In this study the accuracy obtained by Fischer was questioned and techniques were developed to improve on his accuracy. In all, the gait of 65 subjects was investigated. Many more photographs were taken of the subject during one complete cycle of walking. Further, the curves were not smoothed out, since Bernstein felt that the complexity of locomotion would preclude the smoothing out of any curves. Fischer's data for locations of the centers of gravity of the various segments, their radii of gyration, and their relative masses were used in this study. The experiments included investigation of normal walking of men both carrying weights, and unburdened, as well as an analysis of fatigue effects due to these conditions. Mention is made of a volume on the determination of the masses and centroids of the segments of the human body on live subjects, but at the time of this writing such information has not become available to the authors. Mention is made, however, of the fact that differences from Fischer's data were found.

Most recently, Elftman has reported in articles from 1934 to the present, investigations on locomotion including studies of the distribution of pressure in the human foot (11), the function of the arms in walking (12), the force exerted by the ground in

walking (13), the rotation of the body (14), the forces and energy changes in walking (15), the function of the muscles in locomotion (16), and the action of muscles in the body (17).

Elftman has made a valuable contribution to the analysis of problems of locomotion even though he had a limited amount of experimental data at his disposal. Some of the results and conclusions presented were based partly on Fischer's classical experiments and partly on Elftman's direct measurements. The present investigation of locomotion, considered as a three-dimensional process, was undertaken at the suggestion of Elftman.

THEORETICAL ANALYSIS

It has been felt by the authors that a knowledge of the positions of the joints of the lower part of the body and the internal force systems at these joints offer an adequate introductory description of the locomotive process of man.⁴

Fig. 1 is a free-body diagram of the leg during the stance phase of walking, i.e., when the foot is in contact with the ground. The reference (co-ordinate) axes are taken with the origin at the center of the force plate (described in the next section), and are designated by the lower-case letters x , y , and z . Postive co-ordinates denote inward (with respect to the leg investigated), forward, and upward directions. To define the position of a particular point of the leg, appropriate subscripts are used, e.g., x_A , y_A , and z_A are the three space co-ordinates of the ankle joint. The following subscripts are used throughout the paper

F = foot	A = ankle
S = shank	K = knee
T = thigh	H = hip
O = center of pressure on the foot	

The external forces acting on the body during walking are of only two types; (a) gravitational, due to the weights of the various parts of the body; and, (b) reactional, representing the ground forces acting on one or both feet.

The gravitational forces are considered acting at the centers of gravity of the leg segments, and are denoted by W with an appropriate subscript. Thus W_F denotes the weight of the foot, W_S denotes the weight of the shank of the leg, etc.

The ground reactions on the foot are obtained experimentally from a force-plate record and are considered to be applied to the foot at the center of pressure, which is also defined by the force-plate record. As shown in Fig. 1, X_0 , Y_0 , and Z_0 are the components of the ground reaction, and M_{0z} is the torque in the plane of the force plate between the foot and the plate.

The internal forces acting at the leg joints are resolved into components parallel to the xyz reference axes and are denoted by X , Y , and Z , respectively. To define the force acting at a particular joint appropriate subscripts are used, e.g., Z_A denotes a vertical force at the ankle joint, Y_A denotes forward force at the ankle, etc. The sign convention used in the calculations of the joint forces is as follows:

- X = inward force with respect to part of leg below joint.
- Y = forward force with respect to part of leg below joint.
- Z = compressive force (acting downward on part of leg below joint).

The internal moments acting at the leg joints are denoted by M_A , M_K , and M_H , at the ankle, knee, and hip, respectively. These moments are resolved into components about the xyz reference axes and are defined by appropriate subscripts, e.g., M_{Ax} denotes an internal moment at the ankle about the x -axis (a fore-and-aft moment), M_{Ay} denotes an internal moment at the ankle about the y -axis (inward-outward moment), etc. The sign

FIG. 1 FREE-BODY DIAGRAM; LEFT LEG

⁴ A paper describing the energy and power aspects of locomotion is now in preparation.

convention used in the calculation of the internal moments is based upon the "screw" rule, the right-hand rule being used for the right leg, while, for the left leg, the left-hand rule is used, see Fig. 1.

By considering a free-body diagram of the leg below a section cut at a joint, one may state the equations of motion for the free body in terms of forces and accelerations. Using D'Alembert's principle of "equilibrium" of bodies in motion, the internal forces (or moments) at the joints can be expressed directly in terms of reaction forces (R), gravity forces (G), and "inertia forces" (I). Thus may be obtained the relations shown in Table 1. This table shows the reaction, gravity, and inertia terms in summary form for all force components at the joints of the leg. The symbols used in Table 1 and not previously explained are as follows:

- g = acceleration due to gravity
 $\ddot{x}, \ddot{y}, \ddot{z}$ = components of linear acceleration of centroid of segment
 $\alpha_x, \alpha_y, \alpha_z$ = components of angular acceleration of segment
 J_x, J_y, J_z = mass moments of inertia of segment about three axes through its center of mass

EXPERIMENTAL METHODS AND REDUCTION OF DATA

For a complete description of the behavior of the legs of the

human mechanism in walking a knowledge of the forces and moments at the joints is essential. The determination of these forces and moments requires either measurement or calculation of the mass distribution of the leg, displacements and accelerations of the leg segments through one complete cycle, and the reactional forces of the ground on the foot.

Mass Distribution of Leg. The mass distribution of the leg is defined in terms of the weight (or mass), the location of the center of mass, and the mass moment of inertia about the center of mass. To date no adequate method has been presented whereby the numerical values of mass and inertia can be measured accurately from living subjects.⁵ The most commonly used methods are the use of Fischer's coefficients and the Weinbach graphical method (19). Braune and Fischer (8, 9) established coefficients for expressing the relative masses of the segments as compared to the body as a whole, and the position of centers of mass and radii of gyration of the segments as proportional parts of the length of the segment. Although Braune and Fischer worked on a few frozen corpses their results have been accepted and used in most subsequent investigations. According to Fischer, the weight

⁵ A reference to a Russian publication dealing with this subject has come to the attention of the authors, but this is not available in the United States at this time. The reference is given in the Bibliography as item (18).

NOTE: COLUMN (1) = (2) + (3) + (4)

of a segment divided by the weight of the body is a constant C_1 ; the distance of the center of mass from the proximal joint divided by the length of a segment is a constant C_2 , and the radius of gyration of the segment about the mediolateral centroidal axis divided by the length of segment is also a constant C_3 . Thus

- (a) Weight of segment = $C_1 \times$ weight of body
- (b) Distance from proximal joint to center of mass of segment = $C_2 \times$ length of segment
- (c) Radius of gyration, $\rho_x = C_3 \times$ length of segment; hence mass moment of inertia $J_x = \text{mass of segment} \times (\rho_x)^2$

The method proposed by Weinbach is based on the assumption that any cross section of a segment is elliptical and that the density of the body is uniform throughout. The masses, the locations of the centers of mass, and the radii of gyration of the leg segments may be determined by numerical or graphical integration of data obtained from front and side-view photographs of the leg. This method, proposed by Weinbach, is so tedious that in view of the questionable assumptions of ellipticity and uniform density, it was deemed adequate for the purpose of this paper to use Fischer's coefficients of location of centers of gravity, weights and masses, and the radii of gyration.

Calculations for the mass, centroid location, and moment of inertia of the combined shank and foot of one normal subject were made using both Fischer's and Weinbach's methods. All values as determined by Weinbach's methods were less than those by Fischer's method by about 10 per cent of the latter.

In the case of the location of the center of mass of the foot, Fischer's laborious graphical construction was replaced by an arbitrary coefficient. Table 2 shows the coefficients used in the calculations.

TABLE 2 ASSUMED COEFFICIENTS

Member	C_1	C_2	C_3
Body.....	1.0000		
Thigh.....	0.1158	0.44	0.31
Shank.....	0.0527	0.42	0.25
Foot.....	0.0179	0.35	0.30

In order to check the accuracy of the coefficients listed in Table 2, a simple experiment was performed at the University of California.

A subject was seated so that one leg was supported only by a chair, as in Fig. 2. A cable connected to a proving ring was attached to the ankle. Mounted on the same ankle was an electrical accelerometer. The subject, by extending his knee joint, created a tension in the cable which was measured by the proving ring and a recording oscillograph. The moment of this force about the knee was thus determinable from the recorded force and the known distance of the cable from the knee joint. The cable was then cut, with the result that the shank and foot swung upward rapidly. The acceleration of the ankle was recorded on an oscillograph actuated by the accelerometer, and the angular acceleration of the foot and shank about the knee computed.

By assuming that the knee moment (M) supplied by the musculature was equal to the external moment before the cable was cut, the moment of inertia of the foot and shank about the knee J_x' was computed from the relationship

$$J_x' = \frac{M}{\alpha_x}$$

The results of the experiments on three subjects are presented in Table 3.

The fair agreement between the theoretical and experimental values shown in Table 3, together with the small effect of inertia

A. TEST APPARATUS

B. TYPICAL OSCILLOGRAPH RECORD

(see "Results"), would seem to indicate that use of the coefficients shown in Table 2 is sufficiently accurate for purposes of comparison of several subjects.

Displacements and Accelerations. Several methods of defining the displacements, velocities, and accelerations of the joints of the leg were tried. The chronophotographic method of Marey, as improved by Fischer, was improved still further by substituting continuously lighted ophthalmoscope bulbs at significant points on the leg, and taking all pictures in a darkened room. By exposing the film to the lights 30 times each second, a photograph containing many points of light was obtained. With the application of a suitable scale factor the co-ordinates of the lighted joints could be plotted, and graphic or arithmetic methods used to calculate velocities and accelerations. This method was useful only for the side view of the walking operation, since there was no gradual displacement of the body when viewed from the front to preclude overlapping of the point images on the film. In addition, the allowable magnification of the film was too limited to allow of accurate convenient reduction of the data.

For these reasons 35-mm motion-picture photography taken at 40 frames per sec from the front and side, while the subject was walking over a force plate, was used to obtain joint displacements. Targets were placed as close as possible to the most probable locations of the centers of the joints at the toe, ankle, knee, and hip of the leg nearest the side camera. Fig. 3 shows the positions of these targets. The use of targets taped to the skin involves

several limitations, namely, the movement of the skin over the bone causes some slight error in location, and due to the definite thickness of the limbs, the front and side targets will not be at the same elevation when the member is inclined. Since the elevation in the frontal view figures in the determination of lateral movement, while that in the lateral view determines the fore-and-aft

FIG. 3. SUBJECT 4 ON FORCE PLATE

moment, small discrepancies will exist in a comparison of the two components of moment. The resulting film was projected to about one-half actual size and the co-ordinates plotted to a convenient scale. The origin of co-ordinates was taken as the center of the wearing surface of the force plate; the co-ordinate axes were z , positive upward; x , positive inward; and y , positive forward. Figs. 4 to 6, inclusive, show the displacements of the leg joints as obtained from the motion-picture records.

The x , y , z -components of the linear accelerations of the joints were obtained by differentiating twice the curves of the joint displacements with respect to time. In view of the accuracy of the motion-picture data, it was found that graphical differentiation was the best and quickest method and hence was used for determining accelerations.

The co-ordinates of the center of mass of each segment were obtained on the basis of the coefficients given by means of simple equations, for example (referring to Fig. 1 and Table 2)

$$x_S = x_R + 0.42(x_A - x_R) = 0.58x_R + 0.42x_A$$

where

x_S = x -co-ordinate of shank center of mass

x_R = x -co-ordinate of knee joint

x_A = x -co-ordinate of ankle joint

The linear accelerations of the center of mass of each segment were obtained in a similar manner, using the same form as the equations for center-of-mass location, but substituting accelerations for displacements in the foregoing equation.

In order to facilitate the calculations of the location of center of mass and corresponding linear accelerations simple nomograms were used.

The α_x and α_y components of the angular accelerations of each

FIG. 4. FORE-AND-AFT DISPLACEMENT OF JOINTS OF LEG; SUBJECT 1

FIG. 5. VERTICAL DISPLACEMENT OF JOINTS OF LEG; SUBJECT 1

FIG. 6. LATERAL DISPLACEMENT OF JOINTS OF LEG; SUBJECT 1

segment were calculated from the linear accelerations of the two end points of the respective segment, as follows:

The tangential component of the relative acceleration of the upper joint with respect to the lower joint of a particular leg segment is equal to the product of the distance between the joints and the angular acceleration of the segment. The sign convention for the angular acceleration is the same "screw" rule convention as used for the moments.

The effect of the angular acceleration about the z -axis on the moments about the z -axis is very small, and hence was neglected in the calculations. Further, the angular accelerations about the z -axis could not be computed without the aid of measurements of the twists of the segments (21).

Reaction Forces. The reaction forces on the foot were measured on a force plate designed and manufactured under the supervision of Don M. Cunningham at the Artificial Limbs Research Project of the University of California. The lack of moving parts, and the recording of all measurements on an oscillograph tape made this force plate ideal for the problem at hand. The force plate determined the location of the center of pressure, the torque about z -axis, and the vertical and horizontal forces applied to the foot. A paper dealing with the details of the equipment and experimental procedures is now in preparation.

Data Reduction. The computations were set up in a tabular form but, nevertheless, constituted long and tedious procedure. The extent of the work involved in calculating the quantities for only one stride is indicated by the fact that approximately 14,000 numerical calculations were performed, 72 curves were plotted, and 24 curves were subjected to graphic differentiation. This work required approximately 500 man-hours at first but due to increased experience of the reduction personnel the computations for the fourth subject were completed in 250 man-hours.

RESULTS

Displacements. While the subject is walking forward in a relaxed automatic manner, various segments of the body undergo displacements during different phases of a stride. The integrated result of these displacements is a stable, uniform, and mechanically efficient process of locomotion. Some displacements have a definite function in the process of locomotion—such as stabilizing the body during support on one foot, improving efficiency of muscle action, etc. Other displacements have no definite apparent function. A complete description of the kinematics of human locomotion will not be given here, since it is not necessary for analysis of the force system in locomotion. A few brief remarks about the displacement data used for force calculations are, however, in order.

Figs. 4, 5, and 6 show the components of the linear joint displacement of one subject in graphical form. A typical stride shown in these figures consists of a complete cycle of stance (foot in contact with the ground) and swing (foot off the ground) starting at heel strike of the left foot and ending at the next heel strike of the same foot. This cycle takes 1.18 sec, during which the subject moves forward through a distance of 5 ft.

It is apparent from examination of Fig. 4 that the hip moves through 5 ft at about a uniform rate during the entire cycle, while the toe and the ankle move through 5 ft only during 0.4 sec of the swing phase; thus the foot and ankle have larger accelerations than the hip.

Fig. 5 shows the vertical displacements of the leg joints. The rapid toe descent following heel strike, and the toe pickup during the swing phase are clearly apparent. The ankle starts rising just preceding toe-off, and starts descending just after toe-off. Little vertical motion takes place at the knee. The hip joint has a displacement pattern which is typical of joints lying closely to the torso; it has a period half that of the complete stride—the hip rises and falls twice during one complete stride.

The mediolateral displacements of the leg joints are shown in Fig. 6. These displacements are of relatively small magnitude but are of great importance for the stability of the body during normal walking. As the weight is transferred from one leg to the other, the body shifts toward the weight-bearing side. The lateral displacements of the hip joint, shown in Fig. 6, clearly indicate this motion. These data exhibited a large amount of

scatter and the smooth curves representing joint-displacement variation are the best approximations. While the forward and vertical displacement patterns, shown in Figs. 4 and 5, are also represented by smooth curves, the amount of scatter for these data are definitely negligible. In comparing the character of data in Figs. 4, 5, and 6, however, it must be remembered that the displacement scales in these figures vary a great deal. The relative scales of the displacements are 20:4:1 for the forward, vertical, and lateral movements; thus any inaccuracy in the lateral-displacement data is much exaggerated.

It must be emphasized that locomotion involves a very sensitive balance on one foot—it has been previously described as a continuous process of fall and recovery—and therefore small displacements from the position of unstable equilibrium are to be expected. The stability of locomotion is preserved by muscle actions (controlled by nerve impulses) which tend to return the body to the equilibrium position. This results in minute jerkiness of motion which is not ordinarily apparent, but contributes to the scatter of the data. This "jerky" characteristic of locomotion is not reproducible, and the small deviations from the smooth process vary in each step even for the same subject. Since the purpose of this analysis is to consider the forces and displacements involved in a general reproducible pattern of locomotion, it was considered that smoothing out the displacement curves was justified.

Forces and Moments. The results of the computation of the forces and moments at the joints of the same subject are plotted in Figs. 7 and 8. To correlate the variation of the forces and moments with the position of the leg in space, the time of heel strike, toe strike, heel-off, toe-off, and the heel strike of the next stride are shown in the figures.

In order to obtain the over-all system of forces acting on the body, the forces acting on both legs must be considered. The total force on the body can be obtained by superposition of two curves, adjusting the time of beginning of each curve to correspond to the proper phase sequence of motion. This places the heel strike of the opposite leg little less than halfway between heel-off and toe-off of the given leg. (An accurate analysis of the forces acting on the body has been carried out at the University of California using data from two force plates. This analysis has not been included here).

The X -(lateral) components of joint forces shown in Fig. 7 have very small magnitudes. These forces are important, however, in providing the lateral stability in walking and contribute a large share of the lateral hip moment (M_H). As the body weight is shifted from one leg to the other the lateral force must be directed inward with respect to the body (negative X_H), in order to prevent the subject from falling sidewise. The magnitude of this force will depend largely upon the amount of lateral hip motion.

The Y -(fore-and-aft) components of joint forces shown in Fig. 7 have a typical shape approximating a full sine wave during the stance phase. During swing phase, the Y -forces are small and their variations are somewhat irregular. With the sign convention adopted in this analysis, a positive Y -force indicates an external force tending to retard the forward motion of the body. Thus it is apparent that the variation in Y -component of the force on the leg is due to the fact that upon heel strike the leg first must retard the forward motion of the body, and then a fraction of a second later must provide the "push-off" or forward acceleration necessary to continue the motion.

The Z -(vertical) components of joint forces shown in Fig. 7 have a typical double-peak shape; this is due to vertical upward and downward accelerations of the body. The difference between the vertical component of floor reaction Z_0 (very nearly equal to Z_A), and the body weight is proportional to the vertical accelera-

tion of the body. The first peak occurs shortly after heel strike, when the body rolls over the supporting leg, and the other peak occurs when the leg "pushes" the body up just before the other leg strikes the floor.

The differences between the forces at the ankle, knee, and hip joints indicate the effect of gravity and inertia at these joints. Thus the maximum vertical compressive force occurs at the ankle joint, while at the hip joint this force is reduced by the gravity and inertia effects of the shank and thigh. The variation in the X-

FIG. 7 JOINT FORCES; SUBJECT 1
(Time for one complete stride, 1.18 sec.)

FIG. 8 JOINT MOMENTS; SUBJECT 1

and Y-components of forces at the ankle, knee, and hip joints are due to inertia effects only, since gravity does not affect these components.

The X-component of moment shown at the top of Fig. 8 is that component tending to extend or flex the foot. From the adopted sign convention, a positive X-moment would be produced by the resultant force passing in front of the joint. Thus the negative X-moment occurring just after heel strike indicates that the resultant force passes behind the ankle at this time, when the toe is still being lowered. When the foot is flat the load shifts so as to pass ahead of the ankle, yielding positive moment which increases rapidly, reaching a maximum value at the time the subject pushes off on the foot. It is to be expected that the magnitude and timing of the negative moment, occurring when the foot is being lowered, would be a definite aid in diagnosis of such pathological conditions, as, for example, *talus dorsalis* where the foot is allowed to slap down, possibly registering less negative moment over a shorter time than normal.

The X-component of the knee moment registers quite clearly a phenomenon of gait found in nearly all normal subjects to date. The sign of this component of the knee moment is such that, when negative, the resultant force passes behind the knee, tending to flex it (and therefore render it unstable), while a positive moment indicates that the knee is being moved into or held in a "locked" position (stable). Thus, from the curve, one may conclude that at heel strike the leg is quickly stabilized, then unlocked; and once again locked for the push-off phase of the step. This "double-locking" action permits the subject to move forward with a minimum raising of his center of gravity, and therefore with less expenditure of work.

The location of the resultant of the forces at the hip, as partially indicated by the sign and magnitude of the X-component of the hip moment, serves to demonstrate the precept of continual rotation of the body pointed out so clearly by Elftman (14). The initial positive moment at the hip indicates that the forward rotation of the torso is being retarded, while the later change to negative moment indicates the renewal of forward torso rotation.

The lateral components of moment reflect the requirements of bipedal walking on the joints of the leg. In shifting from leg to leg, the torso is shoved first one way then the other, and moments somewhat proportional to the elevation of the joint above the ground are recorded. This points out the relatively large magnitude of the Y-(lateral) component of moment at the hip, a factor beyond the analysis of investigations which have their attention confined to the plane of progression.

The Z-components of moment reflect the positioning of the shears in the leg, and therefore may be associated largely with the twist of the body as well as that of the segments of the leg. Of interest is the fact that the results of pin studies (21) on twist of the segments agree quite consistently in phasic nature with the M_z -curves in Fig. 8.

Fig. 9 illustrates the significance of inertial and gravitational effects on the fore-and-aft moments at the ankle, knee, and hip. The contributions of reactions to these moments at the ankle, knee, and hip are compared to the total computed moments, so that the difference in ordinate between the total moment and the reactional moment represents the effect of gravity and inertia of the segments below the indicated joint. It is apparent from Fig. 9 that the effect of gravity and inertia on fore-and-aft moments is very small for the ankle and knee moments, and relatively small on the hip moments throughout most of the stance phase.

Since the computations of the moments about the joints due to these effects are the bulk of the calculations, a rapid first approximation to the magnitudes of moment and force may be made by considering only the moment due to the floor reactions. In

the case of the hip, however, considerable error may be introduced in such an approximation.

To serve as an indication of the general value of the results for one subject, comparisons of several characteristic joint forces and

FIG. 9 CONTRIBUTION OF REACTIONS: FORE-AND-AFT MOMENTS; SUBJECT 1

moments, computed for four subjects, are shown in Figs. 10 to 14, inclusive. The values plotted are the vertical force at the ankle (Fig. 10), fore-and-aft moments at the ankle, knee, and hip (Figs. 11, 12, and 13), and lateral moments at the hip (Fig. 14). These curves were selected as the most important ones, particularly from the point of view of magnitude. In these figures the time scale is plotted as per cent of the time for one complete stride, in order that the phasic activity of the four subjects can be most closely compared.

The examination of the comparison curves for four subjects illustrates the degree of variation between the individual subjects. Notwithstanding the large variations in magnitudes of the peak values and their phases relative to heel strike, the general patterns of the curves discussed with reference to Figs. 7 and 8 are apparent.

The curves shown are but one way of plotting the results of the calculations. If one chooses to ignore the inertial effects and the weight of the segments of the leg, a very convenient method of representing the results would be that employed by Elftman and his co-workers at New York University. This consists in plotting the positions of the segments in space as lines, and showing the accompanying floor reactions as vectors with the proper magnitude, direction, and point of application. By prolonging the line of action of this force vector, one may note by inspection the orientation of the joints of the leg with respect to the line of action of the ground force. One of the limitations of this method is that the walking cycle must be broken into many small intervals if one is to obtain a reasonable picture of the gait of the individual—a procedure of dubious economy, compared to the instantaneous indications of such curves as are presented herein.

No study of the mechanics of locomotion would be complete

SUBJECT	CODE	HEIGHT	WEIGHT
1	---	5'-11"	165 lbs.
2	---	5'-8"	153

4	---	5'-11"	161

FIG. 10 VERTICAL ANKLE FORCE; FOUR SUBJECTS

FIG. 11 FORE-AND-AFT ANKLE MOMENT; FOUR SUBJECTS

without the mention of the bone forces. Only the muscles at a joint can provide the moments, and since they act only in tension, the resultant force at a joint at the times when moment is evidenced can be compressive only if the bone forces are very high compressions themselves. Since muscles may also act to oppose each other at a joint so that there is no resultant moment, high compressive bone forces may be expected at times when there is no moment. It is not unreasonable to expect that at such times as push-off the bone forces may easily exceed twice the body weight. Inman (20) has investigated forces acting on the femur at the hip joint under several static conditions. He found that under these conditions the force on the femoral head is 2.4 to 2.6 times as great as the body weight, while the tension in the abductor muscles is 1.4 to 1.9 times the body weight. The magnitudes of the lateral hip moment used in Inman's investigation approach closely the peak values computed

FIG. 12 FORE-AND-AFT KNEE MOMENT: FOUR SUBJECTS

FIG. 13 FORE-AND-AFT HIP MOMENT: FOUR SUBJECTS

during level walking, and hence his results are indicative of forces acting at the hip joint during normal locomotion. Eiftman (15) has made some computations of this nature, using such simplifying assumptions as the moment arms of the different muscles, and their time of action. Auxiliary studies of phasic activity of the muscles have shown, however, that any such calculations at this time would be, at best, first approximations.

It is apparent from the foregoing discussion that the variations of forces and moments in the leg joints are closely related to the mechanical functions of the leg in walking. These relationships, in addition to the studies of energy of human locomotion, investigations of the activity of different muscles of the leg, and the anatomical studies of leg-joint mechanisms (1) are necessary in order to solve the problems confronting the orthopedic surgeon and the designer of artificial legs and braces.

Report on Graphitization Studies on High-Temperature Welded Piping of The Philadelphia Electric Company

By J. B. ABELE¹ AND A. E. WHITE²

Summaries of the work which has been done by and for the Philadelphia Electric Company in ascertaining the degree of graphitization in the piping system in the Chester, Schuylkill, and Richmond Stations since the fall of 1946, are reported in this paper. The results of a full-size pipe tension test on a graphitized weld section are reported. Solution treatment for removal of graphitization is described with some physical test results.

SECTION 1 By J. B. ABELE

THIS report is a supplement to one presented in 1946, by Hopping and White,³ and gives results of further studies and investigations covering a period of approximately 2 years. The conclusions of the previous report, based upon the work done up to that time, led to a decision to continue the use of the pipe, and periodically to examine the welds further as a means of comparison and determination of increases, if any, in the formation of graphite. Such findings were to be used as a basis for a decision either to continue the use of the piping in its existing condition or to take appropriate steps to remedy this condition. The piping under investigation was as follows:

Chester Station. Operating since 1941 at a pressure of 1250 psi and 925 F; carbon-moly pipe, killed with $\frac{1}{2}$ lb of aluminum per ton of steel.

Schuylkill Station. Operating since 1938 at a pressure of 1250 psi and 900 F; carbon-moly pipe, killed with 1.8 lb of aluminum per ton of steel.

Richmond Station. Operating since July, 1943, at a pressure of 400 psi and 850 F; carbon-steel pipe. From 1935 to July, 1943, the operating temperature was 875 F with occasional swings to 900 F.

OPERATING RESULTS AT CHESTER AND SCHUYLKILL STATION

Since the previous report, samples have been removed from all three stations for investigation.

At Chester Station, where approximately 20,000 service-hours have been added since the previous report, no appreciable amount of graphite has formed on either side of the welds in the heat-affected zones or in the pipe metal. Previous examinations of

samples from the same welds showed no graphite in either the heat-affected zones or the pipe metal. Samples, however, have been removed from other welds where small amounts of nodular graphite were found. The conclusion, therefore, up to the present time and after 50,000 hr of service, is that very little graphite will form in the welds at Chester Station; however, occasional check examinations will be made in the future.

At Schuylkill Station the situation is somewhat different. Since the previous report, additional samples have been removed. They were taken from welds previously sampled and represent an additional 25,000 hr of service. In two of the samples examined, the amount of graphite in the heat-affected zones appeared to be somewhat greater and more continuous than was found in samples previously examined from the same welds. In another sample, the graphite did not appear to be quite as severe as that found in the sample previously examined from the same weld. In view of these findings, it is intended to remove completely one of these welds for mechanical tests, since metallographic examination does not give a quantitative measure of the degree of deterioration of the properties due to the presence of graphite.

The indicated increase in severity of graphite may be evidence of increased graphitization since the last examination, but this is not conclusive because previous work has shown that the amount of graphite varies considerably around the circumference of the weld. It can be stated, however, that the added graphite, if any, is quite small for the added service period of approximately 25,000 hr. At present, therefore, it is believed that, while there are indications of a slight increase in graphite in the welds at Schuylkill Station, it has not progressed to a point where continued use of the pipe in its present condition would be unwise. The results of future examinations will determine the action to be taken at Schuylkill Station.

It is thought that the small amount of aluminum used in killing the steel for the piping at Chester Station, as contrasted with the larger amount used for the Schuylkill Station piping, is the reason for the difference in the amount of graphite found in the welds at the two stations.

DETAILS OF TESTS AT RICHMOND STATION

At Richmond Station a full section of 20-in.-OD carbon-steel pipe was removed for a tension test. The section was approximately 3 ft long with a weld in the center and was tested on the 4,000,000-lb tension testing machine at the shops of the American Bridge Company, Ambridge, Pa. Fig. 1 shows the specimen before testing. It consisted of the section of pipe, two internally tapered transition rings, and two massive pulling heads. Twelve Baldwin Southwark SR-4 strain gages were used to measure strain. Four gages were placed on the weld, 90 deg apart and 4 gages were placed on the pipe 90 deg apart on each side of the weld.

The cross-sectional dimensions of the pipe, the data developed from the test loading and the strains measured with the SR-4 gages are given in Table 1. Yielding of the steel in the pipe metal on one side of the weld occurred at a load of 1,200,000 lb, which is

equivalent to a stress of 22,080 psi. The strains measured by the SR-4 strain gages on the weld indicate that the weld metal also yielded at this load which is equivalent to a stress of about 19,280 psi in the weld metal. The yielding of the steel in the pipe metal on the other side of the weld occurred at a load of 1,750,000 lb which is equivalent to a stress of 32,200 psi. The elongation measurements are listed in Table 2. It is to be noted that neither set of measurements listed in Table 2 encompass the fracture of the specimen.

The fracture occurred in the weld-heat-affected zone and had three zones of distinctly different appearance; an outer zone of black and gray conchoidal fracture which is identified as graphitized steel extending in varying widths all around the fracture; a zone of a dark fine granular fracture extending around one-quarter of the pipe; and an inner zone, the largest, of a normal-appearing white fine granular fracture. Fig. 2 is a general view of the fracture, and Figs. 3 and 4 are detail views of a portion of the fracture.

From Table 1 it will be noted that the specimen broke in the weld at a load of 2,545,000 lb, equivalent to a fiber stress of 46,830 psi. The original tensile strength of the steel as reported by the mill was 70,900 psi. Probably half of the reduction in strength is due to the annealing effect from a service of 92,000 hr at temperatures ranging from 850 to 875 F, with occasional swings to 900 F. The balance of the reduction to 46,830 psi is due, without doubt, to graphitization. While a stress of 46,830 psi provides an ample factor of safety in a sound weld, resistance to thermal shock is of great importance and provision for this in a weld of this kind is none too good.

The appearance and nature of this fracture led to a decision to correct the condition at the earliest convenient time. Consideration was given to replacement of all the affected piping. An investigation, however, of the steel a short distance from the welds showed that the mechanical properties and the structure of the steel had not been unduly impaired, although the tensile strength had dropped to about 54,000 psi through normal service conditions but with no loss in ductility. It seemed inadvisable therefore to remove the pipe, and consideration was given to the

FIG. 2 GENERAL VIEW OF TEST SPECIMEN AFTER FRACTURE

FIG. 3 DETAILED VIEW OF TEST SPECIMEN AFTER FRACTURE

FIG. 4 DETAILED VIEW OF TEST SPECIMEN AFTER FRACTURE

replacement of the welds or to a solution treatment of the welds to disperse the graphite.

Earlier work in normalizing at 1700 F at the University of Michigan together with more recent work at the same institution convinced us that this method offered a possible effective means of restoring graphitized welds.

SOLUTION TREATMENT TO DISPERSE GRAPHITE

Investigation by A. E. White at the University of Michigan, discussed later on, disclosed the fact that solution treatment, followed by proper stress relief placed the graphitized metal in a safe state of strength and ductility. Therefore, it was decided to repair the pipe by this method rather than replace the welds. The latter method would require more time and involve greater cost.

A careful investigation of the practical application of solution treatment of welds in the field also indicated that the work could be speedily and successfully done.

The procedure finally agreed upon was as follows: Heat to 1700 F at a rate not to exceed 300 deg per hr from 1000 F to 1700 F. Hold at 1700 F for 2 hr. Control cooling from 1700 F to 1200 F at a rate not to exceed 100 deg per hr. Allow to cool, uncontrolled, from 1200 F to approximately 700 F. Stress-relieve by raising temperature to 1275 F at a rate of 400 deg per hr. Hold at

FIG. 5 HEATING ARRANGEMENT ON EXPERIMENTAL PIECE

1275 F for 1 hr per in. of thickness. Cool to 700 F at a rate of 200 deg per hr. Allow to cool uncontrolled from 700 F.

A method of electronic heating was discussed with the engineers of the Radio Corporation of America. This method, however, was not practical because of the mass of metal involved. Calculations indicated that approximately 40 kw of radio-frequency power would be required to maintain a band 6 in. wide at 1700 F in the 20-in.-OD pipe. While it is true that their 75-kw generator would produce enough heat to perform the normalizing treatment, it was felt that the portability and the relatively great expense of the equipment made its use impractical.

Heating with gas was considered, but this too was thought to be impractical since it was felt that it would be difficult to maintain a uniform heat around the entire circumference unless an oven or muffle was built around the pipe. Because of insufficient clearances and other interferences in many cases, such a muffle could not be used.

Induction Method of Heating Pipe. It was finally decided that the induction method was the most logical one to use and, accordingly, experimental tests were run on a short length of 20-in.-OD pipe. Because of the extreme temperature and high amperage required, water-cooled coils were used.

Twelve turns of $\frac{3}{8}$ -in.-OD 0.035-in.-wall copper tubing were used on each side of the welded joint (24 turns total). The turns were arranged so that the cooling water was discharged and fresh water was admitted for each 3 turns around the pipe. Four 60-kva stress-relieving transformers were used, making a total of 240 kva available. They were connected, two in series, to each heating coil with a separate control cabinet for each set of transformers. A water relay was used with each cabinet to shut the power off automatically in case the cooling-water supply failed. The leads between the transformers and heating coils were made up of

four welding leads in parallel 100 ft long. Fig. 5 shows the setup on the experimental piece.

Experiments were also conducted in an effort to determine whether or not scale formation could be prevented or at least minimized. The amounts of scale formed were compared for (1) open-ended pipe with a free circulation of air, (2) dead air by blanking each end of the pipe, and (3) by the use of inhibitors such as helium, nitrogen, and CO_2 . While the amount of scale varied between methods, the total in no case was considered great enough to warrant the use of any of the special methods; the conclusion being that there would be no more scale than is found in the welded joints of a new installation.

Formulating the Solution Treatment. In formulating a program for the solution treatment of the welds at Richmond Station, it was decided to remove additional boat samples from welds representing the various materials and combinations of materials. Samples were removed from pipe to pipe joints both in the 16-in. and 20-in. seamless pipe, and from pipe to pipe joints as well as from longitudinal welds in the 24-in. fabricated pipe. While graphite was found in the 16-in. and 20-in. welds, no graphite was found in the 24-in. fabricated piping, due, we believe, to the high silicon content of the plate material.

In passing, it will be of interest to note that a gas shop weld in the 20-in. pipe was examined and no graphite or other detrimental structural alterations were found in it. It would be unwise, however, to draw too general conclusions from the examination of a single weld.

Material for the castings for the gate and nonreturn valves contained approximately 1.00 per cent nickel, 0.70 per cent chrome and 0.50 per cent molybdenum. No samples were removed from the welds at these valves since it was reasonable to assume that little or no graphite exists on the valve side because of their high chromium content. Also, these welds were to be safeguarded by a solution treatment.

Valve Tests. It was feared that some valve distortion might occur with the 1700 F temperature heat, making it necessary to repair or reseat the valves; therefore, temperature measurements were taken in the castings to provide data for future temperature applications to valve welds. The nonreturn valves are Schutte & Koerting 16-in. double inlet, 20-in. single outlet. Thermocouples placed on the body at the center of the valves during solution treatment of the weld on the 20-in.-diam outlet, which was 28 in. away from the center line of the weld, indicated a temperature of approximately 575 F. Removal of the bonnets of these valves after solution treatment and an examination of the trim, and a subsequent pressure test, showed that there had been no distortion of the seating surfaces. Similarly, thermocouples placed on the body of the 20-in. gate valves, 12 in. from the weld showed a temperature of 800 F. It is evident, therefore, that a temperature of 1700 F at the welding ends of valves of comparable size will not affect the trim of valves adversely.

Some thought was given to adequate bracing of the piping during solution treatment because of the plastic condition of the weld metal and of possible strain in the piping. It was finally decided that no elaborate means of bracing need be used, a decision which proved to be correct.

Electrical Energy for Solution Treatment. Electrical energy for the solution treatment at Richmond Station was delivered through a 600-kva temporary power bank, installed to provide 440-volt 3-phase power from the 2300-volt bus. Temporary feeders were installed to the distribution center located in the vicinity of the work to be performed. The stress-relieving transformers were placed at a central location and connected to the distribution center in such a manner that all transformers on any one joint were all on the same phase. The data in Table 3 show the requirements for heat-treatment.

FIG. 6 TYPICAL NORMALIZING & STRESS-RELIEVING CHART

FIG. 6 TYPICAL NORMALIZING AND STRESS-RELIEVING CHART SHOWING TEMPERATURE AT WELD AND AT VARIOUS DISTANCES FROM WELD

FIG. 7 DIAGRAM OF NORMALIZING AND STRESS-RELIEVING EQUIPMENT

Fig. 6 is a typical time-temperature chart showing the temperatures at the weld and at various distances from the weld during the solution and stress-relieving treatment. Fig. 7 is a schematic layout of the equipment used.

All welds in the high-pressure piping system at Richmond Station were solution-treated with the following exception: The 24-in. fabricated pipe where no graphite was found, and the pipe from the superheater header to the nonreturn valve on one boiler, which was replaced with one-half chrome and one-half moly pipe left over from Southwark Station.

Twenty-Nine Welds Treated. Twenty-nine welds were solution-treated and the work was completed in nineteen 24-hr working days, thus effecting a material time-saving over and above that which would be required were the graphitized welds cut out and replaced with new welds. It is felt, however, that the treatment has removed a latent critical condition, either temporarily or permanently, and substantially prolonged the useful life of this pipe, although it is not necessarily to be construed that this method should be used if graphitization has advanced to an undue degree.

Later samples will be removed from time to time and a future course of action will depend upon the findings.

SECTION 2 By A. E. WHITE

RESTORATION OF PROPERTIES OF GRAPHITIZED WELD SECTIONS BY HEAT-TREATMENT

Mr. Abele has pointed out that this author would deal with the subject of the restoration of the properties of graphitized weld sections by heat-treatment at the Richmond Station of the Philadelphia Electric Company.

The restoration of graphitized weld sections was advanced by the author in 1943, and a report covering some preliminary work in this field was given to the Philadelphia Electric Company on February 5, 1944. The restoration procedure, from a laboratory standpoint, is simple. It merely involves heating graphitized sections above the upper critical temperature for a sufficient time so that all of the graphite will go back into solution, with a time interval at this temperature sufficient to provide for the best possible dispersion of the resultant carbide. In this connection, a temperature of 1700 F continued over a period of 2 hr has been found adequate for graphitized-pipe weld sections.

No claim is advanced that the restoration of graphitized welds by solution treatment, which is the term commonly used to describe the heat-treatment, can be employed successfully in all cases. If the graphitization is too pronounced, some claim small disconnected sections or cavities might remain where the graphite had been, even though the conversion of graphite to carbon was complete. Also, there is a possibility that, due to location, not all types of graphitized welds might lend themselves to a solution treatment. A weld adjacent to a valve might be a case in point. However, as the technique of solution treatment advances, it is expected that less and less difficulty will be encountered in this respect.

With this background, serious consideration was given to restoration of the graphitized welds at the Richmond Station by solution treatment. This was because of the marked degree of graphitization found in a full-size pipe section that was broken at Ambridge, as well as the evidence of considerable graphitization obtained from boat samples and full-size pipe sections which had been removed from service for purposes of investigation.

Prior to the adoption of the solution treatment for the removal of graphite from many of the welded pipe sections, numerous solution treatments were run on small samples to show that the graphite could be put into solution. This was then followed by laboratory solution treatments on tensile specimens, accompanied, in some cases, by stress relief.

A summary of some of the most important of these tests is given in Table 4. It should be noted that the test sections removed early in 1948, for which figures are given in this table, were

* Yield strengths were not obtained on these samples because at the time the tests were made interest centered only on tensile strength, elongation, and reduction of area.

NOTE: A.C. = air cooled.

from a weld which was graphitized to approximately the same degree as existed in the weld broken at Ambridge, which is illustrated in Figs. 2, 3, and 4. These results, together with the complete lack of evidence of graphite in the solution-treated samples, showed this treatment to be so promising that it was adopted as a method of restoring many of the graphitized sections in the carbon-steel pipe at the Richmond Station. The word "many" is used because a few of the graphitized welds, due to location, or some other cause, were removed and replaced by new welded sections.

It will be noted that greater ductility was found in the sample solution-treated at 1600 F than in the samples solution-treated at 1700 F. It was felt, however, that a solution treatment at 1700 F would be preferable to a solution treatment at 1600 F because of greater assurance of a more complete dispersion of the carbides. However, the greater ductility found with a 1600 F solution treatment led this author to suspect that a stress relief would improve the ductility of the metal which had undergone a 1700 F solution treatment. When tried, this proved to be the case and, because a stress relief of 1275 F gave superior ductility to the metal to a stress relief of 1200 F, the former was adopted. The procedure finally adopted, therefore, was to give the graphitized welds a solution treatment at 1700 F for 2 hr, followed by a stress relief of 1275 F for 1 hr per in. of metal thickness.

In the investigation weld-prober samples were taken from two graphitized weld sections and examined at the University to determine which one of the two sections contained the greater amount of graphite. These sections were designated as weld A and weld B. From the graphitization standpoint, little difference was found in the two sections and was less than had been found in other sections previously examined, although weld A appeared to have slightly more graphite than weld B. Weld A, therefore, was the section selected for a solution treatment, with a subsequent stress relief. Both sections were removed from the pipe line and, after weld A was given the solution treatment, followed by stress relief, at the Richmond Station, they were shipped to the University of Michigan for examination.

TEST MATERIAL

The pipe was purchased to ASTM Specification A-106-33T Grade B. The samples were 16 in. diam with wall thickness of 0.745 in. and were 18 in. long with the weld in the center.

The mill analysis was reported as follows:

	Per cent
Carbon.....	0.23
Manganese.....	0.93
Phosphorus.....	0.014
Sulphur.....	0.03
Silicon.....	Not given

The physical properties, as reported by the mill, are as follows:

Tensile strength, psi.....	70900
Elongation in 2 in., per cent.....	35

The average operating temperature of the pipe sections since July, 1943, was 850 F, although from 1935, to July, 1943, the operating temperature was 875 F, with momentary swings to as high as 900 F. The pipe sections had been in service 92,000 hr.

PROPERTIES OF WELD B PIPE

The room-temperature tensile properties of the welded carbon-steel pipe known as weld B are given in Table 5. It will be noted that, although the test specimens included the weld sections and the heat-affected zone sections wherein the most graphite would be found, the specimens all broke in the unaffected-pipe-metal sections. The values in the table, therefore, are more indicative of the values that would be found in the pipe metal than of the values that would be found in the metal in the weld or in the heat-affected zone. Attention is called to the fact that, although the pipe metal was reported as having a tensile strength of 70,900 psi, the tensile strength of the pipe metal after 92,000 hr of service averaged 56,375 psi.

lated to the studies which were made on the section of the welded carbon-steel pipe which was given a solution treatment, followed by a stress relief, at the Richmond Station of the Philadelphia Electric Company. Details with regard to the heat-treatment given this pipe section are covered in the portion of the paper by Mr. Abele.

Test Procedure. The test procedure which was followed in the examination of this pipe at the University was as follows:

- 1 The section of the pipe was cut into longitudinal strips to supply samples for macro- and microexaminations and for tensile tests, as indicated in Figs. 8, 9(a), and 9(b).
- 2 Strips from four quadrants were macroetched the full length of the pipe sample to check the structure at the weld and at the heat-affected zone resulting from the solution treatment.
- 3 Metallographic examinations were made to determine if the graphite at the heat-affected zone of the original weld had been dissolved and to show the microstructure resulting from heat-treatment.
- 4 Tensile tests were conducted at room temperature to establish the physical properties of the metal in the weld area and through the adjacent pipe metal following the solution treatment.

The locations of the tensile test sections are shown in Fig. 9(b). Attempts to force fracture at the outside of the original weld-heat-affected zone, where the concentrated graphite had dissolved, were not successful.

Wherever possible, rectangular test specimens with a gage section 0.50 in. \times 1.25 in. \times 3 in. were used. The pipe sample was so short that it was necessary to use 0.505-in.-diam test specimens when testing the material heated between the critical temperatures during the solution treatment.

GENERAL RESULTS OF STUDY

Physical Tests. The results of the tensile tests on the solution-treated pipe given in Table 6 indicate that the solution treatment and stress relief produced a material with satisfactory strength and ductility. The following additional comments are offered:

1 When the gage section of the test specimens was placed across the weld, the weld-deposited metal was the weakest, and fracture occurred at that point. The area where graphite had originally been concentrated, the coarse-grained area, had the higher strength.

2 When samples were machined (A2-10D and A3-3U) which covered the zone from the weld to a point where the temperature reached the upper critical temperature during solution treatment, the strength and ductility were both higher than that in the weld metal. It was not possible to force fracture at the region of graphite concentration before solution treatment in order to determine the ductility at that point.

3 The metal heated between the critical temperatures had strength about the same as the weld metal and somewhat lower elongation. This comparison is not to be interpreted too literally because, in order to test this section, it was necessary to use 0.505-in. test bars, whereas the other test bars were 0.50-in. \times 1.25 in. \times 3 in. The important point is that this portion of the solution-treated pipe had adequate strength and ductility.

4 Test data are not available for pipe metal heated at the lower critical temperature or the pipe metal not affected by the solution treatment, as the length of pipe supplied was cut just beyond the point where the temperature reached the lower critical.

As removed from service, there was very little difference in the amount of graphite in the two weld sections submitted for this investigation. Weld A had, at most, only slightly more graphite than weld B. Therefore the graphitization in weld A before solution treatment can be inferred to be about the same as that in weld B. The results of the tensile tests as given in Table 5 for weld B, therefore, can be assumed to be representative of what the tensile tests would show for weld A before solution treatment.

Although none of the samples broke in the heat-affected zone in any of the tests reported in Tables 5 and 6, it is evident

that the solution treatment did not affect the properties of the metal adversely in the weld areas as a result of the conversion of the graphite in the heat-affected zone. This statement is made in spite of the rather large grains found in the heat-affected zones, which resulted from the very slow cooling of the metal during the solution treatment, as shown in Fig. 11.

It is believed that if a more rapid rate of cooling from the solution-treatment temperature had been adopted, a fine-grained

structure would have resulted as has been the case in all of the samples which were laboratory solution-treated.

Macrographic and Metallographic Studies. Macroetching of samples from quadrants of the pipe section known as weld A give the results shown in Fig. 10.

Metallographic examination of this same weld area gave the following results:

1 No graphite could be found at the location of the original heat-affected zone. Slow cooling during the solution treatment produced annealed types of structures.

2 A band of comparatively coarse grains was located parallel to the weld and at a location believed to be that of the outside edges of the heat-affected zones of the original weld where the more concentrated graphite had formed during service. Fig. 11 is representative of both the upstream and downstream weld-heat-affected zones of all four quadrants of the solution-treated pipe. Fig. 12 is fairly representative of all of these sections before solution treatment.

The band of comparatively coarse grains shown in Fig. 11 is believed to be due to the slow cooling to which this pipe was subjected following its heating to 1700 F. Had the rate of cooling been more rapid, equivalent to that used in normalizing, it is believed that a normal fine-grained structure would have resulted.

Naturally, during the solution treatment, a temperature gradient would exist from the center of the weld along the pipe in both directions. The zones in these different gradients were examined but nothing of moment was found, although mention is made of a graphitelike substance found about 1 in. from the heat-affected zone which showed slight discontinuities.

CONCLUSIONS

The field solution treatment resulted in the metal in the weld zone having the same strength and ductility at room temperatures as was found in the original pipe metal after it had been subjected to service for 92,000 hr. As was expected, the weld-

deposited metal was the weakest. The strength values were somewhat lower than those which previously have resulted from laboratory normalized samples because the heat cycle of the field solution treatment involved cooling rates slow enough to anneal the metal.

Graphitization during service had not been severe enough to affect the strength of the welded section given a solution treatment.

×100

×1000

FIG. 12 MICROSTRUCTURE OF UPSTREAM AND DOWNSTREAM HEAT-AFFECTED ZONE OF WELD-PROBER SAMPLE 15R
(Sample removed prior to field solution treatment. Sample fairly representative of all four quadrants.)

No evidence was observed to indicate that the solution treatment had increased the amount of graphite in the pipe metal.

Finally, although the physical properties of the solution-treated weld section were not materially different from those in the untreated weld section, because the amount of graphite in the untreated weld section was not sufficiently great to have any influence on the properties of the sections in question, yet, it is believed that the treatment was worth while in that it converted any possible concentrated graphite to a carbide, with a resultant good dispersion of the carbide, and thus would restore any badly graphitized sections to a serviceable condition.

In conclusion, it should be pointed out that this treatment is not one which will effect a cure, but one which will permit the continued use of the pipe for possibly as long as it had been used previously. As stated by Mr. Abele, however, in his portion of the paper, these solution-treated sections, as well as all welded sections, should undergo inspection at suitable intervals in the interest of safety.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Mr. E. L. Hopping, Consulting Engineer, Philadelphia Electric Company, for his counsel, encouragement, and continued support to this program. Also, grateful acknowledgment is made to the field organizations of both the United Engineers and Constructors Inc., and the Philadelphia Electric Company for the constructive work done in the development of field methods which made the heat-treatment procedure so successful. Acknowledgment is further made to Dr. J. W. Freeman, research engineer, Mr. J. J. Heller, and others of the Engineering Research Institute, for their co-operative services.

Discussion

F. EBERLE.⁴ This paper is of considerable practical importance in that it shows a possibly effective procedure of solution-heat-treating weld joints which are not too severely graphitized, thereby giving them, so to speak, a new lease on life. The authors used room-temperature tensile tests in conjunction with microscopic examination to evaluate the existing degree or extent of graphitization, low elongation and reduction of area plus failure in the zone of graphite concentration being the in-

⁴ Chief Metallurgist, Research and Development Department, The Babcock & Wilcox Company, Alliance, Ohio.

indicator of a potentially hazardous condition. This method of examination undoubtedly will reveal whether there is any danger to be expected due to shock, as illustrated by the original Springdale failure; but one may question whether it will also indicate the further behavior of such a graphitized weld joint at operating temperature when it is not exposed to shock. Therefore, it may be of interest to present here the result of a creep test which was made with a specimen containing a graphitized carbon-molybdenum pipe weld in the center of the gage length.

Fig. 13 of this discussion shows the condition in the weld-affected zone of the sample prior to creep testing. This pipe joint had been in service for 5½ years at a temperature of 930–950 F. Graphitization, though discontinuous, was considered at that

FIG. 13 WELD-HEAT-AFFECTED ZONE OF CREEP-TEST SPECIMEN
PRIOR TO CREEP TESTING
(Nital etch; ×100)

time severe enough to remove this joint from service. The specimen prepared from it was tested at 1000 F under a load of 5000 psi, which is the maximum allowable working stress given by the

Boiler Code. We kept this specimen under test for 40,200 hr, during which it displayed the following rates of creep, expressed in per cent per 100,000 hr:

	Per Cent
0 to 15000 hr.....	0.7
15000 to 31000 hr.....	0.8
31000 to 40200 hr.....	0.5

Fig. 14 shows the condition of the weld-affected zone after termination of the test. It will be observed that the manner and extent of graphitization is now in every respect as severe as it was in the original failed Springdale pipe. The graphite is seen to be almost totally concentrated in the grain boundaries, forming

a continuous chain through the entire cross section of the specimen. One cannot help wondering why the latter did not rupture. It certainly would appear from this example that there is little likelihood of immediate danger at operating temperatures for weld joints in which graphite is present in a discontinuous manner, provided of course that they are not exposed to shock.

It may be necessary sometimes to make a decision as to whether a weld joint may be permitted to continue in service for a certain length of time before remedial measures are taken. To our knowledge, there are no means or methods of predicting safely if and within what length of time a discontinuously graphitized weld-affected metal will develop dangerous graphite concentration

or continuous grain-boundary chain graphite. The authors of the paper have observed that graphitization in some field welds was found to have increased very little, if at all, when checked again after 25,000 hr.

Our own graphitization studies have led us to believe that stress is one of the most important factors in promoting graphitization, and the outstanding factor in causing the formation of grain-boundary chain graphite. We are of the opinion that the graphitized weld from which the previously discussed creep-test specimen was prepared would not have deteriorated to the same extent as the latter if it had been exposed to the same temperature and for the same length of time in the unstressed condition. Elimination of stress concentrations in the weld-heat-affected metal, therefore, appears to be of paramount importance if the formation of dangerous graphite concentration or of grain-boundary chain graphite is to be avoided. A normalizing treatment followed by thorough stress-relieving would appear to be a step in this direction.

It seems to us that the effectiveness of restoring graphitized weld joints by this method will depend not only upon the complete solution of the existing graphite but also upon the effective dispersion of the locally dissolved carbon by diffusion.

Figs. 15 and 16 show the weld-heat-affected zone of the previously described creep-test specimen after a 2-hr solution heat-treatment at 1700 F, following termination of the creep test.

It will be noted that some graphite remained undissolved throughout the entire cross section and, more important yet, that microfissures formed at locations where massive graphite went into solution. These microfissures were identified as such by the seepage of drying alcohol, and the resulting staining during microscopic examination. We are presenting this extreme case as a matter of general interest only.

H. J. ROBAR.⁵ Early in the investigation of graphitization of welded pipe sections we, among many others, considered solution of the graphite by heat-treatment as a means of restoring ductility to severely graphitized zones in the C-Mn pipe and castings. In 1944 H. Weisberg reported that normalizing at temperatures up to 2200 F did not materially improve the ductility of the graphitized zone in the Springdale pipe or in a 12-in. cast valve, both of which were severely graphitized. Additional data, summarized in Table 7 (page 49), have been obtained since that time, and indicate that when the graphite is of the chain type or when the nodules are closely spaced, normalizing or normalizing and tempering does not improve the ductility appreciably. The ductility of more mildly graphitized sections, however, is considerably improved.

A miniature bend test was used in determining ductility, for

138.2D	"	Heavy; medium size nodules as short chains and aggregates.	None	0.3" long crack at 6% elongation.
138.2DN	"	Same as 138.2D.	1700 F for 2 hr, air cooled.	Cracking started at 11.8% elongation, at 15.4% elongation crack was 0.38" long.
138.2DNT	"	Same as 138.2D.	1700 F for 2 hr, air cooled, 1275 F for 2 hr, air cooled.	Cracking started at 10% elongation, further bending increased extent of cracking.

the only available material was small boat-shaped probes cut out of pipe joints. The test specimens, $\frac{1}{8}$ -in.-thick center sections of the probes, were bent in a guided-bend test jig along the zone of graphitization. Fiber elongation was measured on a $\frac{1}{2}$ -in. gage length.

Heat-treatment does not restore ductility to all graphitized zones, because a residue of unknown composition remains after the solution of the graphite. When the graphite is of the chain type, the residue exists as an irregular fine line; if the graphite is nodular, the residue is nodular, annular, and/or crescent-shaped. It is because of this similarity in form between the residue and the graphite that the ductility of severely graphitized sections is not restored by solution heat-treatment.

Concomitant with the foregoing study, the possibility of re-graphitization after solution heat-treatment was investigated. Specimens of varying degrees of graphitization were solution-heat-treated, as shown in Table 8 (page 48) of this discussion, and then maintained in an oven at a temperature of 1000 F for 6000 hr. Subsequent metallographic examination disclosed that all specimens had graphitized again and to approximately the same degree that existed before solution treatment. Fig. 17 herewith illustrates the degree of graphitization before heat-treatment, after solution treatment and degree of re-graphitization in the 6000-hr period:

Based upon these results, we have not resorted to solution heat-treatment as a means of rehabilitating graphitized welded sections. Our practice has been to cut out and reweld those joints that are severely graphitized and of poor ductility. All welded sections in old specification pipe and all castings are of course probed at suitable intervals.

I. A. ROHRIG.⁶ The authors are to be commended for the information they have contributed on the subject of heat-treatment of welded joints in high-temperature main steam piping. Their method of accomplishing the heat-treatment has been outlined clearly, and their test data show that graphitized welded joints can be reconditioned suitably for further service, provided the graphitization has not become critical.

Work of the same nature has been done by the writer's company, and the results are in general agreement with those presented by the authors. An account of this study has been given by D. H. Corey and the writer.⁷ By the use of this method normalizing of graphitized welded pipe joints while in position has been carried out by the writer's company since early in 1947.

The tensile-test data given in the paper show that the ductility of the graphitized welded joints used for test was improved markedly by heat-treatment. The data, however, apparently do not reveal the ductility of that part of the sample which is of greatest importance, namely, the graphitized zone. The paper states, "Attempts to force fracture at the outside of the original weld-heat-affected zone where the concentrated graphite had dissolved were not successful." What is required, therefore, is a test that can be applied to the graphitized zone.

The bend test mentioned by Mr. Weisberg in his discussion of an earlier paper⁸ meets this requirement reasonably well. That test indicates in a quick and simple manner the relative bend ductility of the graphitized zone. It has been used in the Research Department of The Detroit Edison Company with satis-

factory results in evaluating the condition of graphitized welded joints. The apparatus used in the Research Department in performing the bend test consists of two dies, similar to those

FIG. 21 BEND-TEST SPECIMENS FROM WELDED JOINT IN MEDIUM-CARBON-STEEL PIPE

shown adjacent to the lower die in Fig. 19. Note that the specimen which was cut from a weld-prober sample removed from a graphitized welded joint has cracked badly in the graphitized zone.

The specimens shown are $\frac{1}{8}$ in. thick and are finish-ground on both faces. Slight etching before test readily reveals the outline of the weld and facilitates positioning of the specimens in the dies so that the bending can be made to occur in the graphitized zone. The results obtained by means of the bend test may be stated in terms such as, length and width of cracks after bending, angle of bend, elongation of the bent area, or gage pressure. Some of the results obtained from this test may be of interest. Bend-test specimens of medium-carbon steel representing various conditions of heat-treatment are shown in Fig. 20.

Severe cracking occurred in the graphitized zone of specimen (a) and in the formerly graphitized zone of specimen (b), when bent. Specimen (c) which had been furnace-cooled, exhibited

satisfactory ductility as did specimens (d) and (e), which had been drawn at 1200 F and 1275 F, respectively.

The bend-test specimens shown in Fig. 21 also were taken from a medium-carbon-steel welded joint removed from service.

Although specimen (h), which had been furnace-cooled after 2 hr at 1700 F, had much better bend ductility than specimens (f) and (g), it exhibited a crack in the formerly graphitized zone. Specimen (i), which had been drawn at 1100 F, cracked badly in the affected zone. This fact indicates that a draw treatment at 1100 F may cause brittleness in the formerly graphitized zone. Samples (j) and (k), which had been drawn at 1200 F and 1275 F, respectively, did not crack even when bent 110 deg. The single heat-treatment, consisting in heating at 1700 F for 2 hr, followed by slow cooling, produced good improvement in ductility as determined by the bend test. Further improvement in ductility of joints so treated could be expected as a result of the annealing effect of service at 800 to 900 F.

The results of the bend test, which was made on the samples described herein, are in agreement with the tensile-test results given in the paper, in that the best ductility was obtained by employing a draw treatment at 1275 F, following the 1700 F solution treatment.

The primary purpose of this discussion, however, is to point out that the bend test has the advantage in that the testing force can be applied to the significant area, i.e., the graphitized zone.

AUTHORS' CLOSURE

The authors are grateful to Messrs. Eberle, Robar, and Rohrig for the contributions made to their paper through their discussions.

They are in agreement with the thought expressed by Mr. Eberle, that stress concentration in weld-heat-affected zones appears to be of paramount importance in the formation of dangerous graphite concentrations or of grain-boundary chain graphite. They have never found in their examinations of graphitized metal, after a solution treatment, as large an amount of what we may speak of as "constituent X"—that is, voids, graphite, inclusions, or occlusions, as shown in Fig. 15. As a matter of fact, they have not found any evidence of constituent X in any of the heat-affected zones following solution treatment in the plain carbon steel reported in this paper. They have found constituent X in the carbon-moly steel, in the heat from which the 12-inch pipe was made in the main steam line in the Schuylkill Station, though it was smaller in amount and in particle size than that shown in the photomicrographs in Fig. 16 of Mr. Eberle's discussion. The evidence of constituent X at the time the paper was given was not pronounced. Also, the constituent X was not of a chain-like type.⁹

The authors are grateful for the valuable contribution of Mr. Robar. They recognize that solution treatments would not materially improve the ductility of graphitized zones in pipe as severely graphitized as was the case with the Springdale pipe. Also, they have found that the graphite has a tendency to return to the locations in which it was found after several thousand hours of heating. They have never held that solution treating was a cure, but a method which might be employed for prolonging the useful life of graphitized pipe, provided the graphitization has not developed to too great a degree.

The authors also appreciate the contribution of Mr. Rohrig which so completely described the bend test procedure used by The Detroit Edison Company.

⁹ A recent further examination of carbon-moly welded pipe which had been solution treated, that was made nine months after this paper was presented, shows in one of the quadrants of a heat-affected zone a constituent X somewhat similar to that shown in Fig. 16 of Mr. Eberle's discussion.

The authors' feeling with regard to the solution treatment is summed up by Mr. Abele in his statement to the effect that "The treatment has removed a latent critical condition, either temporarily or permanently, and substantially prolonged the useful life of the pipe." This statement, of course, relates to the pipe that had undergone graphitization at the Richmond Station. It

does not necessarily hold, however, for all graphitized plain carbon pipe.

Also, the feeling of the authors is covered in the statement by A. E. White to the effect that "No claim is advanced that the restoration of graphitized welds by solution treatment can be employed successfully in all cases."

Development of the Hydraulic Design for the Grand Coulee Pumps

By CARL BLOM,¹ LOS ANGELES, CALIF.

The Grand Coulee pumping plant has been the subject of an extensive hydraulic research program. The first part of this program was conducted at The California Institute of Technology for the Bureau of Reclamation from January, 1938, to July, 1940. Some of the results of this program have already been published (1 to 4),² and other papers (5, 6) describe the different features of this project. This paper presents some of the results of continued experimental research of the author's company from 1943 to 1946. The investigation covered the effects of various diffuser-type pump cases and impellers on the pump characteristics of the Grand Coulee model. The paper concludes with the description of the final test of the contractor's model completed in July, 1947.

PRELIMINARY INVESTIGATIONS AND OPERATING REQUIREMENTS

IN a paper by E. B. Moses (5) is described the development of the Grand Coulee Project in detail. A brief summary of the pumping plant will be reviewed here for ready reference. The pumping plant is situated at the Grand Coulee Dam on the Columbia River in the State of Washington. This huge pumping plant will consist of twelve vertical single-stage pumping units. Each unit will be driven by a 65,000-hp motor, or a total of 780,000 hp for the complete pumping plant. The pumps will have a wide operating head range, from 365 to 270 ft, with a corresponding capacity of 1100 cfs to 1650 cfs, when operating at the constant speed of 200 rpm. The pumps will be of the vertical single-stage single-suction type, with 12-ft-diam discharge, and a 14-ft-diam suction.

The Grand Coulee Project makes one feel the daring of its conception, the overwhelming grandeur of its size and power, and last but not least the painstaking care given to the investigation of all its details. In order to obtain strict and exacting final specifications, a research program lasting 2½ years was conducted at the Hydraulic Machinery Laboratory of the California Institute of Technology (later called Cal Tech), sponsored by the Bureau of Reclamation (later called The Bureau), and carried through with the co-operation of three pump manufacturers.

The foregoing program was considered necessary even though the investigations and test results of the large pumping units (7, 8) for the Metropolitan Water District of Southern California were available. No part of the research program mentioned would have been effective in detail without the development of Cal Tech Hydraulic Machinery Laboratory (9), with its precision instruments and exact measurements to aid in securing the effect of small design changes.

The final specifications called for a minimum flow rate of 1350 cfs at a rated total dynamic head of 310 ft, and a minimum war-

ranted pump efficiency of 87 per cent at this point. Furthermore the specifications require a minimum flow rate of 800 cfs at a total dynamic head of 365 ft, and a maximum load not to exceed 65,000 hp at 270 ft total dynamic head. The great variations of head and flow rate had to be obtained at a constant speed of 200 rpm. The specifications also prescribe that the head-capacity curve shall be relatively steep, and the pump efficiency as high as possible over the entire range of operation. The pump shall have stable operation free from cavitation within the full range of operating heads.

PUMPING-PLANT LAYOUT AND HEAD VARIATION

Each pumping unit will pump through separate piping systems (see Fig. 1). Each system consists of the trash rack, intake structure, a 90-ft-long 14-ft-diam suction pipe and elbow, and an 850-ft-long 12-ft-diam discharge pipe. The water surface at the intake to the pumping plant will fluctuate from a maximum elevation of 1290 to a minimum of 1208, that is, a total difference of 82 ft. At the same time the water surface at the outlet will vary between the elevations of 1571 and 1557, a difference of 14 ft.

The foregoing head variations, and the pipe-friction loss, also shown in Fig. 1, and the static water-surface elevation from the intake to the outlet lead to a variation of total dynamic heads from a minimum of 270 ft to a maximum of 365 ft, or an operating range from 100 to 135 per cent. The most severe suction conditions occur at low capacities when the water surface at the intake is at an elevation of 1208. The center line of the pump is located at an elevation of 1203, which provides only a 5-ft submersion for pumping heads from 365 ft down to 350 ft.

NEED FOR FURTHER INVESTIGATIONS

Difficulties were encountered when the former test results were applied to our investigation of a pumping unit of minimum weight and cost. Early weight calculations eliminated the most attractive case type, that is, the double-volute case. This type satisfied all the requirements of the specifications. However, the weight became excessive because of the heavy reinforcing needed to maintain permissible stresses in the open section. Unlike this, the diffuser-type case, in which the diffuser vanes act as connecting members between the two side walls, leads to a lighter pump case and thereby to the most economical unit.

In the original model study, pumps with diffuser cases gave a very unstable performance near the 365-ft operating head. The problem therefore was to design a diffuser-type case which would meet all the hydraulic requirements and particularly have stability of performance near the high operating head. This unstable portion of the pump characteristics was greatly affected by the pump-case design and had not been overcome satisfactorily by the preliminary experiments with diffuser-type cases.

Further investigation was also necessary owing to the wider operating head range given in the final specifications. The original model study conducted at Cal Tech from 1938 to 1940, was based upon a total head variation from 295 to 365 ft, or a total operating range from 100 to 125 per cent, while the final specifications call for an operating range of from 100 to 135 per cent.

FIG. 1 SECTIONAL ELEVATION OF GRAND COULEE PUMPING PLANT

As these and other problems became more evident soon after Byron Jackson Co. and The Pelton Water Wheel Company decided to make a joint bid, they initiated in 1943, a program of development. This program assigned to Byron Jackson Co. the task to design, build, and test models in order to develop the final hydraulic lines of the pump. The investigation was conducted at Byron Jackson Co.'s plant from 1943 to 1946, and carried to a successful completion in spite of war and postwar difficulties.

At the end of the investigation a bid was submitted and resulted in the award of a contract to build six pumping units. After the award the research program was continued at Byron Jackson Company's plant and, at the same time, it was decided to conduct the final acceptance test at Cal Tech. It was deemed advisable to take advantage of the precision test facilities at Cal Tech because of the magnitude of the project and the desirability of having impartial observers. Also, the big prototype-to-model ratio of 13 to 1 made it imperative that tests should be conducted with the greatest possible accuracy.

PRESENTATION OF TEST DATA

Before going into the details and comparisons of test results at the different stages of development, the following differences of presentation are noted. The preliminary tests at Cal Tech and some of the tests by the author's company were made with model units of greater size than the final ones used for acceptance tests. The reason for this was that the horsepower available at Cal Tech was not sufficient to run the original model at speeds corresponding to the operating heads in the field. The specifications called for tests at field heads. Furthermore, in the final model the casing was built with sectional breaks in curvature, corresponding to the welded structure of the prototype case. This was a deviation from the earlier models which were all furnished with smooth pump cases and were of a larger size. Unfortunately, time did not permit us to duplicate the final model with a smooth casing so that the friction losses in the two cases might have been compared.

In the original testing program from 1938 to 1940, the suction-head reading was taken at the suction flange, and the discharge head reading 10 diam beyond the end of the discharge

FIG. 2 HEAD-RECOVERY AND DISCHARGE PIPE BEYOND CONE

cone of the volute, giving afterward a credit for the friction loss in the 10-diam-long pipe. In the final specifications, however, the suction-pressure readings were to be taken at the extreme end of the suction elbow, thus charging the pump with the loss through the elbow.

Another change in the specifications calls for measurements of the discharge head at the end of the diffuser-case cone where the velocity distribution is far from uniform, while the velocity head is figured from a uniform velocity arrived at by dividing the capacity with the area. That there is an apparent gain in discharge head further downstream figured on this basis is shown in Fig. 2.

To determine the amount of this gain in discharge head, a set of readings was taken on a model with a 10-deg-discharge cone at the end of the cone, and 3.4 and 6.8 diam beyond the cone. These readings showed a substantial gain at 6.8 diam beyond the end of the cone, and so justify the Hydraulic Institute's recommendation of measuring the head at a point 10 diam beyond the cone. However, the specifications permitted lengthening of the discharge cone by reducing the total cone angle, thereby obtaining much more uniform velocity distribution at the end of the cone.

In the last models a discharge cone with a 3-deg total cone

angle was used, and head readings obtained at the end of this cone were slightly lower than readings obtained with a 10-deg cone at a point 6.8 diam beyond the end of the cone.

Owing to these different definitions and measurements of total head, the different performance curves are not directly comparable. No attempt was made to recalculate the performance curves and bring them to the same basis, but performance curves shown on any one figure were obtained with the same test procedure and are directly comparable.

For convenience of comparison, most of the model test data were converted into prototype values at an operating speed of 200 rpm. Also, it was found most practical to compare the pump characteristics at an operating point of 1450 cfs at 310 ft. This point gave the same percentage of safety above the minimum required capacity of 1350 cfs at 310 ft as the power percentage safety below the maximum permissible power requirement of 65,000 hp at 270 ft.²

For better understanding of the various performance curves, the main dimensions for the various model impellers and pump cases referred to in the various figures are given in Table 1. All models were mounted horizontally and were of a construction as shown in Fig. 15.

Following is a description of the step-by-step development of various pump cases and impellers to arrive at the smallest pump size and highest pump efficiency unit having a stable noncavitating performance curve under all operating conditions.

PUMP-CASING STUDY

The pump casing represents a high percentage of the total pump weight and, as previously mentioned, the diffuser-type casing proved to be lighter than the single- and double-volute case. However, the pump characteristics with a 12-vane diffuser-type case had not proved satisfactory. Therefore, a continued study of various types of diffuser cases was necessary.

The effect of the pump-casing type on the head-capacity characteristics is shown in Fig. 3. Here the same impeller was tested in two pump cases, a double-volute case with a volute area of 21 sq in. and a 12-fixed-vane diffuser case with a diffuser entrance area of 20.8 sq in. The double-volute-case performance meets all the requirements with a stable head-capacity curve over the operating range, and also exceeds the minimum pump efficiency of 87 per cent at the 310-ft operating point. The 12-vane diffuser case, however, has an abrupt drop in head near the 365-ft head, and the pump efficiency at the 310-ft operating point is

² To permit simplified test procedure and also to eliminate the possibility of cavitation, all performance tests were run with a constant net positive suction head of 115 ft.

FIG. 3 EFFECTS OF CASING TYPE ON PUMPING CHARACTERISTICS

below the minimum 87 per cent required. This drop in head also affected the brake horsepower, and this unstable portion of the performance curve was considered too close to the 365-ft head for safe operation. The foregoing performance curves indicate that the lower number of diffuser vanes would give a more stable and, in general, a more satisfactory performance.

In order to determine the influence of diffuser-case entrance area on the pump characteristics, a series of tests were run with a gradual increase of diffuser-case entrance areas, using the same impeller for all tests. In Fig. 4 is shown the effect of diffuser-vane inlet area on pump characteristics for model pumps using the same impeller and the same 12-fixed-vane diffuser case as described and illustrated in Fig. 3. The diffuser-case inlet area was changed from A to B, which latter is 18 per cent larger than A. Alternating the diffuser-vane inlet area also affects the diffuser-vane entrance angle, but experiments have shown that the area affects the pump performance to a much greater degree than the diffuser-vane angle. The increased diffuser-vane entrance area improved by several points the pump efficiency at 310-ft head, but the head-capacity curve dropped below the 365-ft head. Therefore this performance curve was not acceptable, and further study of the 12-fixed-vane diffuser case was abandoned.

Next a design study was made of fixed-vane diffuser cases with 3, 4, 5, and 6 diffuser vanes, in order to analyze the practical

FIG. 4 EFFECTS OF DIFFUSER-INLET AREA ON PUMP CHARACTERISTICS

FIG. 5 EFFECTS OF NUMBER OF DIFFUSER VANES ON PUMP CHARACTERISTICS

minimum number of vanes which would give sufficient strength and allow a substantial weight saving and still meet all requirements. This study proved that the 6-vane diffuser case was the most satisfactory.

Fig. 5 shows comparison of pump characteristics for 6 and 12-fixed-vane diffuser cases. Here the same impeller was tested in the two diffuser cases, both having practically the same diffuser-vane inlet area but different diffuser-vane outlet areas as shown in Table 1. The 6-vane diffuser case improved noticeably the head-capacity performance near the 365-ft head and materially reduced the dip in the unstable range. The pump efficiency at the 310-ft operating point for the 6-vane diffuser case showed only a slight gain over the 12-vane diffuser case. However, the pump efficiency at that point was later improved. This was accomplished partly by increasing the diffuser-case inlet area which was permissible with the 6-vane diffuser casing, as this casing still gave a stable characteristic at the 365-ft head.

Next, the change of performance with increased outlet area of the diffuser cases was determined. As might be expected, the larger diffuser cases with lower velocities permitted a greater head recovery at the end of the diffuser vanes and therefore showed

some improvement in the pump efficiency. However, this would have resulted in too large a pump case, and therefore further study was continued in order to improve the pump efficiency with the small diffuser case.

New-Type Diffuser Case. By studying the flow distribution in the outlet of the pump-discharge cone for a 6-vane diffuser case, it was found that the higher velocities crowded toward the outside of the pump casing. To obtain a more uniform flow at the end of the discharge cone, several ribs were tried in the pump casing. The best result was obtained when using one rib dividing the flow in a diffuser case into two separate streams similar in principle to a double-volute case. This rib design is shown in Fig. 6. The location of the dividing rib may also be seen in Fig. 7 which shows the final model on its base in the laboratory with the front half of the case removed but with impeller diffuser ring and dividing rib in place.

The velocity distribution at the end of a 3-deg discharge cone for a 6-vane diffuser case, with and without a dividing rib, is shown in Fig. 8. The effect of this dividing rib on the pump characteristics, resulting in increased head and higher efficiency, is shown in Fig. 9.

The same tests were repeated on 6-vane diffuser cases, with and without dividing rib, the cases having a total cone angle of 10 deg, and the results were relatively the same. In the two sets of tests, the gain in pump efficiency and head for the case, with a dividing rib as against the case without this rib, was greater than the energy difference calculated by the integration of the velocity heads corresponding to the different velocity distributions, Fig. 8.

It will be noted that the first three diffuser vanes remain the same in the two pump cases with and without the dividing rib. The difference in performance obtained by these two pump cases therefore can only be the result of what happens beyond the outlet of the third diffuser vane. From this point on, in the case without the dividing rib, the streams from the 4th, 5th, and 6th diffuser vanes flowing into the stream from the first three diffuser vanes must introduce shock and mixing losses which are greater than the friction loss from the two separate streams in the case with a dividing rib. This result was somewhat surprising, since the dividing rib decreases the hydraulic radius of the case.

By continued use of this reasoning, the best results should perhaps be obtained by separating all the streams coming from the diffuser vanes. But such a diffuser case would become impractical to manufacture and, undoubtedly, the further decrease of the hydraulic radius would result in greater friction losses which would offset the gain in reduced mixing and shock losses.

No further tests were made to clear up this point. The improved efficiency in the larger diffuser case previously mentioned, undoubtedly was the result of longer diffuser vanes, although in that case we dealt with diffuser cases with lower velocities. Hence the results are not directly comparable.

EFFECTS OF IMPELLER-DISCHARGE VANE ANGLE ON PUMP CHARACTERISTICS AND PUMP SIZE

Three impellers, having the same profile but with $26\frac{1}{2}$, $23\frac{1}{2}$, and $18\frac{1}{2}$ deg discharge vane angles were tested in a 6-fixed-vane diffuser case. The pump characteristics of these three impellers are shown in Fig. 10. In this particular case, it was more advantageous to present the actual model performance curves, as they more clearly indicate the spread in the head-capacity performance.

The impeller with the $26\frac{1}{2}$ -deg discharge vane angle will require a multiplying factor of 11.4, while the impeller with an $18\frac{1}{2}$ -deg angle requires a multiplying factor of 12.3 of this larger model, or, converted into weight, the impeller with the lower

FIG. 9 EFFECTS OF CASING SEPARATING RIB ON PUMP CHARACTERISTICS

FIG. 10 EFFECTS OF IMPELLER-OUTLET VANE ANGLE ON PUMP CHARACTERISTICS

angle would result in a 25 per cent heavier pump case than an impeller with the steeper angle.

However, the head-capacity performance near the 365-ft head became more unstable for impellers with steeper vane angles. The unstable part of the curve for the $26\frac{1}{2}$ -deg vane angle was considered the upper safe limit for an impeller with this profile. Therefore, to allow for a certain margin of safety in the unstable range, the final model pump was designed with impellers having outlet discharge vane angles of 24 deg. Also, impellers with wider profiles were tested in wider diffuser cases, but these casings had the same diffuser inlet area as the narrow diffuser casings. The wide-profile impeller gave the same type of performance as a narrow-profile impeller with steeper vane angle. No noticeable gain in pump efficiency was obtained with the wider impellers.

EFFECTS OF IMPELLER-VANE ENTRANCE ANGLE ON CAVITATION PERFORMANCE AND PUMP CHARACTERISTICS

Impellers with different impeller-eye profiles were designed and tested to determine the effect of the ratio between radial and peripheral eye velocities on the cavitation performance. In this study it was found that the information given in C. A. Gongwer's paper (2) was very useful, and the best cavitation performance was obtained with an impeller-eye profile which agreed with the formula recommended in that paper.

The effect of the impeller-entrance vane angle on the cavitation performance and pump characteristics is demonstrated by two impellers, A and B, tested in the same 6-vane diffuser case with a separating rib. The two impellers have practically the same profile and outlet vane angle (see Table 1). The main differences in design are the impeller-entrance vane angles as shown on the diagrams in Fig. 11.

FIG. 11 ENTRANCE VELOCITY TRIANGLES FOR IMPELLERS A AND B

Impeller A, with entrance vane angles 28 deg at the eye and 48 deg at the hub, favor shock-free operation at the larger capacity, while impeller B, with vane entrance angles of 21 deg at the eye and 33 deg at the hub, will give shock-free operation at lower capacities.

Fig. 12 shows the result of cavitation tests for these two impellers. Impeller A does not satisfy the minimum σ requirement for the lower capacities at 365 and 350-ft head but, as expected, gives ample safety at the larger capacities, particularly for the capacity at 270 ft. Impeller B, however, satisfies all requirements, but the amount of safety of course is less at the larger capacities.

The pump characteristics of the two impellers are shown in

Fig. 13. A comparison of these two pump characteristics shows that the impeller-vane entrance angle also has an amazingly great effect on the pump performance. The lower impeller-vane en-

FIG. 12 EFFECTS OF IMPELLER-ENTRANCE VANE ANGLE ON CAVITATION CHARACTERISTICS

FIG. 13 EFFECTS OF IMPELLER-ENTRANCE VANE ANGLE ON PUMP CHARACTERISTICS

trance angles on impeller B have also several beneficial results on the pump characteristics, as follows:

- 1 Lower head and brake horsepower at the closed valve, which latter would result in less starting-torque requirement for the motor if started under shutoff conditions. The lower head may be the result of less back pressure created by the lower vane angle at zero and low capacities.

- 2 The unstable portion of the head-capacity curve and brake horsepower moves to a lower capacity with a flatter impeller-entrance vane angle and allows for greater safety of stable operation near the 365-ft head. It is interesting to note in the previous figures shown that the unstable performance caused by the pump casing remains at the same capacity from one type of pump case to the next, and the case design affected only the magnitude of the dip in the head-capacity curves. This also held true in the unstable portion of the brake-horsepower curve. As the lowering

of the impeller-entrance vane angles moved the unstable portion of the head-capacity curve as well as the brake-horsepower curve to a lower capacity, this would indicate that the unstable portion in the performance is the result of flow conditions in the impeller eye.

3 The improved pump efficiency over the operating range, particularly at the lower capacities, gives a strong indication that for pumps designed for a definite operating point, in this case, for instance, 310 ft, the impeller should have vane entrance angles giving a velocity diagram similar to impeller B, rather than the conventional diagram as obtained by impeller A. The suction approach and the NPSH available must of course also be given consideration in the selection of the impeller-entrance vane angles. For commercial pumps, however, which must cover a wide range of capacities it probably will be found necessary to use impellers with vane entrance angles similar to those used in impeller A, as this steeper vane entrance angle has a greater safety against cavitation at the larger capacities.

The final model used for acceptance tests incorporated all the improvements mentioned, and the following résumé will give the results of the final acceptance tests.

MODEL-PUMP TESTS

Final model tests were conducted by the Cal Tech Hydrodynamics Laboratory. Laboratory equipment, except for slight modifications, was the same as previously described in detail (9).

Specifications No. 1128 of the United States Department of the

FIG. 15 ASSEMBLY, GRAND COULEE MODEL PUMP

FIG. 14 GRAND COULEE MODEL PUMP
INSTALLED IN CAL TECH LAB

Interior, Bureau of Reclamation, under which the contract for the six 65,000-hp pumps was awarded, required, in addition to characteristic and cavitation tests, the determination of the following:

- 1 Amount of unbalanced side thrust on the impeller.
- 2 Distribution of flow and amount of prerotation at the eye of the impeller.
- 3 Velocity distribution at the end of the casing extension diffuser.
- 4 Pressure variations near the periphery of the impeller in both the top and bottom covers.

The final model, set up for test in the Cal Tech Hydrodynamics Laboratory, is shown in Fig. 14. The long stainless-steel casing extension diffuser is shown, with discharge piezometer connections at the upper end. A portion of the converging-cone suction elbow, together with one of the balance lines from the back of the impeller to suction pressure, also will be noted in this illustration.

Fig. 15, the model pump assembly, shows the location of both suction and discharge piezometer connections and also the Pitot-tube plates used in the determination of velocity distribution. Piezometer connections, as shown, are located in accordance with the specifications.

From Figs. 14 and 15 it may be seen that the heads and efficiencies obtained in these tests, and reported herein, are not those of the model pump alone but include losses in the suction and discharge piping between the piezometer connections and the pump.

CHARACTERISTIC AND CAVITATION TESTS

All testing was performed at heads equal to those of the prototype, necessitating operation at 2600 rpm, i.e., prototype speed of 200 rpm multiplied by the model ratio of 13. Results of characteristic tests are plotted in Fig. 16 on which a scale has been added for prototype capacity, obtained by multiplying model capacity by the cube of the model ratio, and the inverse ratio of the operating speeds. In accordance with the specifications, the efficiencies shown are those obtained by the model and include losses in suction and discharge piping between piezometer connections. Furthermore, model efficiencies are shown as applying to the prototype, unlike turbine practice wherein an increase is permitted due to decreased relative roughness and clearances.

The test installation included a scale model of the trash rack and inlet structure of the prototype, enclosed in a pressure tank to permit varying the suction pressure (see Fig. 17). The width of the channel ahead of this trash rack was restricted by side plates to that equivalent to one bay in the Grand Coulee wing dam. Water flowing into this channel was passed through a gravel-bed filter having sufficient resistance to insure uniform flow, in an effort to duplicate, as nearly as possible, suction conditions obtaining in the prototype. The entire suction from the trash-rack structure to the pump duplicated that of the prototype to a model ratio scale of 1 to 13.

Table 2 is a comparison of model test results with specification requirements.

The minor discontinuity in the head-capacity curve, indicating unstable operation, falls well outside the operating range of the prototype.

The test results show the model ratio of 13 to be ideal in that it permits minor variations, either smaller or larger, due to manu-

TABLE 2 COMPARISON OF MODEL TEST RESULTS WITH SPECIFICATION REQUIREMENTS

	From Fig. 16	Required by specifications	Safety above requirements, per cent
Cap. at 365-ft head.....	1087 cfs	800 cfs (min)	36
Cap. at 310-ft head.....	1450 cfs	1350 cfs (min)	7.4
Eff. at 310-ft head.....	88.9 per cent	87 per cent (min)	2
Bhp at 270-ft head.....	60100	65000 max	7.5

facturing tolerances in the prototype, without falling short of the minimum required capacities or exceeding the maximum permissible horsepower.

Cavitation performance is shown in Fig. 18 for each of four operating conditions, i.e., the maximum head, the minimum head, the normal (or warranted) head, and a head corresponding to low water in both the lake and the discharge canal. The operating range shown is based on prototype performance, lake levels on the suction side, discharge canal levels, and anticipated conduit and entrance and exit losses. Upper and lower limits of this operating-range area are based upon high and low water

FIG. 18. CAVITATION CHARACTERISTICS OF FINAL MODEL

in the discharge canal, and right and left limits are based on high and low water in Lake Roosevelt. These tests show a margin of safety between the operating range and the inception of cavitation sufficient to exclude the possibility of cavitation damage.

UNBALANCED SIDE THRUST ON IMPELLER

The direct measurement of the amount of unbalanced side thrust on the impeller of a pump, operating at 2600 rpm and 355 bhp, presents numerous difficulties, aggravated by the requirement to make the measurements on a model which in its final form had only 0.007-in. diametral clearance between the rotating and stationary seal rings. Therefore it was decided that the deflections of the pump shaft during operation would be measured; which, combined with the spring constant of the shaft determined at rest, would permit accurate calculation of the forces causing the deflection.

To measure the deflection of the shaft during operation, two insulated metal probes were inserted at points 90 deg apart through holes in the suction cover. A suitable bracket was provided for each probe to hold it in position and at the same time permit fine control of its movement, toward or away from the impeller seal ring. A dial indicator reading to 0.0001 in. was rigidly mounted on each bracket and used to determine the location of each probe. Contact with the impeller seal ring was determined by neon bulbs operated by transformers through a low-voltage trip circuit (see Fig. 19).

It was possible accurately to locate the center position of the impeller with the pump filled with water and slowly rotating so that side thrust was negligible. Then, with the model operating at full speed, deflection readings were taken at various capacities. The resultants of these readings, at the proper angle with the model center lines, are plotted in Fig. 20.

FIG. 19. SETUP FOR MEASURING DEFLECTION AT IMPELLER, GRAND COULEE MODEL

FIG. 20. DEFLECTION AND RADIAL THRUST OF FINAL MODEL

Determination of the spring constant of the model shaft, while at rest, with a beam and weights, permitted the calculation and plotting of the lower curve in Fig. 20, radial thrust versus capacity. The radial-thrust scale for the prototype was obtained by multiplying the model thrust scale by the ratio of areas, that is, the square of the model ratio.

From this curve it may be seen that the maximum radial

thrust under any operating condition, to be encountered in the prototype, is less than 9000 lb and the maximum at shutoff head is only 43,000 lb. This is considered insignificant in a unit of this size having a shaft nearly $2\frac{1}{2}$ ft diam and an impeller which weighs nearly 30 tons.

DISTRIBUTION OF FLOW AND AMOUNT OF PREROTATION AT EYE OF IMPELLER

The velocity and direction of flow of the water entering the impeller were determined by a direction-finding Pitot tube inserted into a plate located approximately 2 in. ahead of the impeller, as shown in Fig. 15. Five traverses were made in each direction. Readings were taken through the entire cross section and results plotted. Numbers on the isovelocity diagrams in Fig. 21 indicate velocity in feet per second.

Velocities on these diagrams are unusually uniform and corroborate the wisdom of The Bureau in the choice of a converging-cone elbow for the pump suction. There is no backflow and consequently no prerotation within the normal operating range for the prototype.

VELOCITY DISTRIBUTION AT END OF CASING-EXTENSION DIFFUSER

Velocity and direction of flow of the water leaving the casing-extension diffuser were determined by a direction-finding Pitot tube inserted in a plate similar to that used on the suction side, except that four traverses instead of five were made in each of two directions at 90 deg. The plate used is illustrated in Fig. 22 with a Pitot tube inserted through one of the holes. Note the cir-

cular scale with a vernier to determine accurately the direction in which the impact hole in the tube is pointed. A scale on the mounting head permits determination of the location of the impact- and static-pressure holes with respect to the center of the pipe. This plate may be seen installed in the discharge line at the end of the upper casing-extension diffuser in Fig. 14.

Results of readings taken at the highest head, normal or guaranteed head, and lowest head, are shown in Fig. 21. Numbers indicate velocity in feet per second.

At the guaranteed point of 310-ft head, the unit produces approximately 0.6 ft more head than it can be credited with owing to additional kinetic energy available in excess of that based on uniform velocity. This may be proved by integration of the velocity-distribution chart for 310-ft head.

PRESSURE VARIATION NEAR PERIPHERY OF IMPELLER IN BOTH COVERS

Pressures were taken at 12 piezometer connections in each cover (see Fig. 23), at operating heads of 365 ft, 310 ft, and 270 ft, and results plotted in Fig. 24. Velocity and direction of flow were not measured. However, the result of the change in the absolute angle of the water leaving the impeller is clearly indicated by the reversal of high- and low-pressure points between the maximum and minimum head conditions.

CONCLUSIONS

The pump-casing type has a great influence on the pump performance, as pumps with single-volute, double-volute, and

FIG. 21 VELOCITY DISTRIBUTION IN SUCTION AND DISCHARGE OF FINAL MODEL

FIG. 22 PITOT-TUBE PLATE FOR DISCHARGE PIPE

diffuser casing designed on the same basis will give different performances. Furthermore, the number of diffuser vanes in the diffuser case has a definite influence on the unstable portion of the performance curve. Fewer diffuser vanes reduce the magnitude of the dip in the head-capacity curve. The diffuser-case inlet area affects the shape of the head-capacity curve and also the pump-efficiency curve. Six diffuser vanes seem to be the minimum number for practical design of a welded pump-diffuser-casing structure, which will give the casing sufficient strength and also allow a substantial reduction in weight. A dividing rib in the diffuser case gives better velocity distribution and improves the pump efficiency.

Impellers with the same profile, but with different impeller-outlet vane angles, materially affect the pump size and weight. The steeper vane angle gives a flatter performance curve and produces a more pronounced dip in the unstable head-capacity range.

The impeller-inlet vane design has a great influence on the cavitation characteristics and also affects the unstable portion of the head-capacity and horsepower curves. A flat entrance vane angle reduces the head and horsepower at closed valve and also improves the pump efficiency at lower capacity.

The unusual performance of the Grand Coulee pumps was a challenge to existing knowledge and techniques. To obtain the desired results, careful testing was required, and the use of the latest testing equipment was necessary. It is hoped that the work presented will be useful and will be followed by detailed disclosures in similar pump studies.

ACKNOWLEDGMENT

The Bureau of Reclamation started the Grand Coulee model test study which was conducted at The California Institute of Technology. Without this basic study the final results of the model would not have been possible.

The author is indebted to Mr. L. N. McClellan, Chief Electrical and Mechanical Engineer of the Bureau of Reclamation, and to Mr. I. A. Winter, Senior Engineer of the Bureau of Reclamation, for technical advice and assistance, as well as to Mr. E. B.

Discussion

I. A. WINTER.⁴ This paper presents some of the outstanding results of experimental research as applied to the development and construction of large centrifugal pumping units. It is of particular interest to the utility engineer since it presents basic research data on construction features related to the pump-impeller design. The importance of the hydraulic designs of the inlet and discharge to the pump casing, and to the casing itself, are presented in the text of the paper and in the comprehensive list of illustrations. The continuity of the presentation is excellent and the material selected is pertinent.

The difficulty of obtaining a satisfactory mechanical design of pump casing of the size and for the pressure required for the Grand Coulee development indicated that some form of diffuser casing would offer the most economical construction. The testing program of the Bureau was directed toward establishing the feasibility of such a design. It had been the general policy of the pump designers of this country to consider the turbine or diffuser casing detrimental to the performance of the pump, although, until recently, it had received wide application in important European installations. It was generally believed that the introduction of vanes in the line of flow opposite the impeller discharge would result in a loss of from 3 to 5 per cent in pumping efficiency. The initial tests at the California Institute of Technology on diffuser casings resulted in the development of designs which

gave efficiencies and capacities equal to and exceeding, in some cases, the performance of single-volute casings.

Further development work, as will be noted by comparing the curves shown in Figs. 25 and 26 of this discussion, resulted in obtaining performance with the diffuser casing equal in all practical

FIXED-VANE DIFFUSER CASING

Fig. 25

DOUBLE VOLUTE CASING

Fig. 26

respects to the performance of the double-volute casing without the use of an auxiliary splitter as described by the author. The difference in performance between the double-volute casing and the 12-fixed-vane casing, as shown in Fig. 3 of the paper, undoubtedly could be considerably reduced by the use of a larger casing, which would provide for greater expansion in the first stage of diffusion. The author's study and development have been quite properly directed toward obtaining the maximum performance for the minimum mechanical equipment. It is likely that any appreciable improvement in pump performance above that presented by the author would be obtained at an increase in cost inherent with the construction of larger equipment.

The development of a satisfactory recovery of velocity head within a diffuser casing requires two separate and distinct stages. The first stage is developed within the diffusers opposite the periphery of the impeller and provides an outflow area 2.4 of the inflow area as described later. The second and final stage is in the conventional conical discharge nozzle also having an outflow area 2.4 of the inflow area for optimum performance. The casing channel at the end of the diffusers, because of the transfer of momentum opposite each diffuser, collects the fluid into a stream having a velocity distribution at the end of the last diffuser vane favorable to the recovery of pressure head in the expanding diffuser of the pump discharge nozzle. Experiments have indicated that the efficiency of a straight conical diffuser is greatly influenced by the distribution of flow at its inlet, and the best design of casing would have a well-distributed velocity relation.

FIG. 27 DESIGN DETAILS

at this point. The diffuser-type casing offers the best possibilities in this regard.

The initial design of diffuser casing prepared by the Bureau was on the basis of turbine draft-tube practice utilizing the principle shown in (b) of Fig. 27 herewith. The basic diffuser for both casings had a nominal outflow area of 2.4 of the inflow area which represents the optimum amount of negative acceleration which can be obtained in a single stage of diffusion, as determined when the change in momentum of the stream within a closed conduit exactly equals the change in pressure. The number of vanes placed around the casing was selected to obtain an optimum ratio of height to breadth of water passage at the outflow in conformance with the best practice in fluid mechanics.

Two methods of balancing the pressure and discharge throughout the 360 deg of impeller periphery were investigated. The first casing provided for a variable amount of expansion in the diffuser ring with the greatest rate of expansion in the diffuser immediately following the tongue of the casing, because of the greater amount of friction head developed beyond this point. The estimated loss of pressure throughout the entire casing at rated capacity was approximately 2.20 ft, and therefore it was necessary to provide 2.20 ft greater recovery of velocity head in the first diffuser, as compared to the last diffuser. These adjustments were made on all vanes in a manner which would produce the same effective pressure around the periphery of the impeller thereby minimizing the amount of unbalanced hydraulic side thrust and creating substantially a uniform rate of flow through the various passages of the impeller.

It is possible that the sudden change in pressure within the passages of an impeller, as the vanes pass the tongue of the pump

casing, may be one of the contributing factors to excessive cavitation and vibration. A sudden change in velocity of flow through a pump impeller when created by a change in pressure would have a cavitation effect because of the presence of inertia similar to that of a vibrating column as used in commercial cavitation-testing apparatus. The favorable sigma value obtained with the 12-vane diffuser casing in the initial tests, where the pressure around the impeller was substantially uniform, lends support to this concept.

Further investigations of the optimum design of diffuser casings resulted in the development of the method shown in Fig. 27(a). The purpose of this design is also to compensate for the losses in pressure head around the periphery of the impeller due to friction. The equalizing effect is accomplished within the casing proper by the transfer of momentum from the relatively higher velocity jets issuing from each consecutive diffuser to the slower moving fluid having been discharged into the casing from previous diffusers. This method may be compared to the transfer of momentum and conversion to pressure of fluids as utilized in jet-pump designs whereby the momentum of one mass is transferred to a second mass having a lesser velocity in accordance with basic laws. The momentum theory states that $M_1 + M_2 = M_3$ or $Q_1 V_1 + Q_2 V_2 = Q_3 V_3$, that is, the velocity after mixing

$$V_3 = \frac{Q_1 V_1 + Q_2 V_2}{Q_3}$$

is illustrated in Fig. 27(a).

The momentum transfer design of casing requires that the difference in velocity head, as represented by the momentum and

pressure formula between each adjacent vane, will be equal to the friction head developed in the distance corresponding to f , as shown on the diagram of Fig. 27(a). This procedure differs from the one previously described in the respect that the recovery of velocity head required to compensate for the loss of friction head in the corresponding section is created in the casing, whereas in the first design, the recovery was effected within the first-stage diffuser ring.

After completion of the tests on the vanes with varying clearances between the impeller and diffuser entrances, the vanes were cut off at the discharge edge until the outflow area of all diffusers were equal. The test on the altered diffuser ring did not result in any noticeable change in pump performance, and it is concluded that the refinement resulting from variable length diffusers is not justified. The author has apparently come to the same conclusion as the illustrations indicate that all six diffusers of the final design are identical. Initial results did not indicate that the principle of the first design was important and the second lacks experimental confirmation. The proposed methods, however, serve the purpose of arriving at a design of casing based on sound engineering principles.

A casing designed to equalize the pressures around the pump impeller, independently of the friction developed within the casing, has been designated as a "compensated" casing and differs from the conventional casing without a diffuser ring approximately as shown in Fig. 27(c). Comparing the compensated casing, having an optimum amount of diffusion in the first stage with the casing described by the author, indicates that a proper design of 12-vane diffuser ring would require a somewhat larger casing than the conventional casing. It is likely that the difference in performance between the 6 and 12-vane diffusers, as shown in Fig. 5 of the paper, may be the result of an inadequate amount of diffusion in the first stage, and to the small hydraulic channels external to the diffusers. Early experiments with rings of various diameters would indicate this possibility.

The author refers to the difficulty of developing the desired pumping capacity under the wide range of effective heads required for the Grand Coulee development. During the early stages of the preliminary investigations conducted by the Bureau, it was realized that this objective may not have been possible of attainment. Accordingly, the prime movers for the Grand Coulee pumps were purchased with provisions for variations in speed of 15 per cent above and below normal so that the best speed for pump operation could be obtained. Results of the investigations made to determine the effect of a change in speed of the pumping unit on the steepness of the head-discharge curve are presented in Figs. 25 and 26 herewith. These data show that the steepness of the head-discharge curves may be affected appreciably by changing the speed of the unit.

On the basis of the preliminary experiments, the specifications for the pumps required that satisfactory operation be obtained at constant speed throughout the full range of pumping heads. It was contemplated that the successful bidder would select characteristics whereby the rated speed of the unit was increased above the normal optimum speed in an amount which would result in the desired operating characteristics within the specified range. It was realized that the required performance would be obtained at an increase in cost of the pumping equipment since the capacity of the pump is lessened as its speed is increased. This, however, was considered to be a proper approach to the problem since it offered means of operating the pumps at synchronous speeds from commercial electrical distribution systems at all times. This flexibility was highly desirable because of the possibility of utilizing excess energy for pumping which might be available from associated generating plants. It was also realized that some doubt would develop regarding the hydraulic performance ob-

tainable over such a wide range of head, and the minimum acceptable warranty of efficiency was lowered accordingly.

The author has further explored the possibility of increasing the steepness of the head-capacity curve, as shown in Fig. 4 of the paper, where it is evident that an adjustment at the entrance edge of the diffuser considerably affects the steepness of the head-capacity curve. Some of the differences shown in this curve may be due to an increase in radial clearance between the periphery of the impeller and the entering edge of the diffuser vanes.

In turbine practice it has been established that the clearance between the movable and stationary vanes should not be less than 4 per cent of the diameter of the runner at the vane tips. In the experiments conducted by the Bureau, a similar relation was found to exist for pumps. The first model tested used a diffuser vane having a clearance at the periphery of the impeller of approximately 3 per cent of the impeller diameter. The performance was erratic and generally unsatisfactory. The vanes were then cut back until a clearance of approximately 4 per cent of the impeller diameter was obtained, and satisfactory performance resulted. Further cutting of the vanes resulted in a loss in pump performance.

The difference in the slope of the head-capacity curves shown in Fig. 3 of the paper, may be due in part to the influence of the volute and diffuser vanes upon the characteristics of the flow as it leaves the pump impeller. It will be noted that the slope of the curve for the double-volute casing is somewhat more favorable than that of the fixed-vane diffuser casing. Best results are obtained with a fixed-vane diffuser if velocity traverses are first made to determine the exact angle of discharge from the impeller while it was being operated in a single-volute casing and the entrance to the diffusers designed to accommodate the actual measured angle of flow. It is not believed that the calculated angle is sufficiently accurate for the purpose of designing the entrance to the diffusers.

The wide range of development work described in the paper is the result of an interest in the Grand Coulee pumps and related engineering development work considerably beyond the requirement for the manufacture of adequate pumping equipment. The author and his associates are to be highly commended for the professional attitude manifested in this important undertaking and the industry, as a whole, is indebted to this symposium for the presentation of the engineering problems and their solution in connection with the world's outstanding pumping development.

R. T. KNAPP.⁵ This is an exceptional paper, not only because it presents the performance of an exceptionally good pump, but also because it gives in detail the steps taken and the reasons for taking them in the design and development program that led to this very successful result. Both the author and his company are to be congratulated on their achievement and their farsightedness in making this technical information available to the engineering profession. The writer is confident that this policy of free exchange of knowledge will prove to be of benefit not only to the engineering profession at large, but also to the individual organizations contributing to it.

The writer would like to emphasize one point brought out by the paper. It should be remembered that the diffuser-case design was selected for the Grand Coulee pumps, not for hydraulic reasons but to secure greater mechanical strength and lower cost of manufacture. These factors were of major importance in this installation, both because of the tremendous size of the pump units and also because of the exceptionally low cost of electric power for their operation. From an hydraulic point of view, it is nearly certain that if the double-volute design could have been

⁵ Director, Hydrodynamics Laboratory, California Institute of Technology, Pasadena, Calif. Mem. ASME.

used, somewhat better performance characteristics would have been obtained; specifically, the head-capacity characteristic would have been somewhat steeper, and the average efficiency would have been slightly higher. Therefore, although this design of the Grand Coulee pump represents a sizable step forward in the development of the diffuser-case volute pumps, it does not mean that it will now become the cure-all for all pump problems. Diffuser-case pumps now simply join the ranks of good design, superior for some applications, of equal merit with different types for other installations, and inferior to other designs for still other requirements.

It is interesting to note that the Grand Coulee pump departs quite radically from all previous diffuser-case designs employed in American and European practice. Although this design is described as a diffuser-case pump, it is truly a cross between the normal fixed-vane diffuser design and double-volute case. As such, it has some of the merits of both. One of the fundamental virtues of the double-volute type of design is that it establishes two symmetrical discharge zones around the periphery of the impeller, and thus creates automatically a balanced system of radial forces for all conditions of flow. The separating rib of the Grand Coulee pump divides the case very effectively into two symmetrical volutes, each containing two fixed diffuser vanes. This geometrical result is shown very clearly in Fig. 6 of the paper. Furthermore, Fig. 20 gives the measurements which show the effectiveness of this construction in securing low radial thrusts for all values of discharge.

There is another aspect of this pump that deserves emphasis. Up until very recently most pumps, large or small, have been purchased from specifications which required given performance characteristics at one operating point only. Specifications might also request a certain general shape of the head-capacity curve and describe other desirable operating characteristics. Contrast this to the requirements for the Grand Coulee machine. Here the minimum capacities are specified at two widely separated heads. The minimum efficiency is specified at one of these heads and the maximum brake horsepower is specified at still a third head. Furthermore, the pump must operate over this entire head range with complete freedom from cavitation. It would seem that this represents a definite trend for the future requirements which will be set up for large units. Such pumps are truly "tailor-made" to fit the measurements of the installation. The Grand Coulee pump is a fine example of how good a fit the manufacturer can obtain for his customer with the help of a well-planned and executed design and development program.

The writer must confess to some amusement concerning the dilemma in which both the manufacturer and the purchaser found themselves concerning the measurement of discharge head. The resulting solution might be called the triumph of specifications over good engineering judgment. As can be seen from the paper, the test results established quite clearly that for the velocity distribution existing in the diffuser a short 10-deg diffuser followed by a length of full-diameter pipe was a little more efficient energy converter than the long 3-deg diffuser. Nevertheless, to meet the specifications the manufacturer is required to furnish a long diffuser and the purchaser to install it even though he thereby secures a slightly less efficient installation than if he had accepted the original design. This minor incident does not detract from the remarkably fine co-operation between the purchaser, the manufacturer, and the laboratory that existed throughout this successful development program.

A. J. STEPANOFF.⁶ The testing program reported by the author

⁶ Development Engineer, Ingersoll-Rand Company, Phillipsburg, N. J. Mem. ASME.

was initiated with the intent to find a better type of pump to meet special conditions of one particular installation. However, the problems investigated are of general interest and deal with the most intimate design features for which it is possible to build up a theoretical background and in this way to make results applicable to different types.

The following points are of particular interest to the writer: The first deals with the moot question of the impeller-inlet conditions. In a great majority of existing designs the impeller-inlet angles are "exaggerated," or are considerably higher than those required for "shockless" entrance at the best efficiency point. The reason for such design can be traced to a quite common misconception that exaggerated inlet angles improve cavitation qualities of the impeller. Although a larger area for the relative flow accompanies higher inlet angles, this may not produce a greater flow for a fixed net positive suction head because a sizable portion of this area is not available to the flow on account of a bad (high) angle of attack. The author's tests prove this. This has been known for some time to the leading pump manufacturers.⁷

On the entrance-velocity triangles *A* and *B*, Fig. 11 of the paper, the author selects the vane-inlet angles for the impeller eye and hub diameters in such a way that the two lines intersect on figure *A* about 14 deg to the right and on figure *B*, 16 deg to the left of the vertical axis, both at capacities corresponding to the head of 310 ft. This latter is not a best efficiency or design point. The objection to such an arrangement is that by allowing the same linear prerotation or the same tangential component of the absolute velocity (c_{u1}) for two different diameters would require a different angular velocity for these two streamlines. Assuming the same pattern of flow will extend to the center of the eye, this would result in an infinite angular velocity there. This is hard to visualize in view of a constant angular velocity of impeller causing this prerotation.

A much simpler pattern of flow and a simpler rule for layout of impeller-inlet angles is obtained if the two lines representing the impeller vane angles are made to intersect on the vertical axis shown in Fig. 28 herewith. Then a desired degree of prerotation is obtained by moving point of intersection *D*, or changing the ratio P_{12}/c_{m1} , where c_{m1} is the meridional velocity at the best efficiency point. This ratio can be established experimentally for different suction-nozzle designs. Thus for horizontally split double-suction pumps, this ratio, being a measure of the degree of prerotation, is within the limits 1.25 to 1.42. For pumps with end suction nozzle, like the author's pumps, lower values should be used. If the velocity triangles in Fig. 11 of the paper are redrawn to comply with the foregoing method, and keeping the same angles at the impeller eye (28 deg for *A*, and 21 deg for *B*), the ratio $P_{12}/c_{m1} = 1.41$ for *A*, and 1.115 for *B* are obtained. The

⁷ The National Transit Pump and Machine Company, in its Bulletin 6000, 1947, p. 4, states that the minimum net positive suction-head requirement is accomplished by "using lowest practical impeller-vane inlet angles" and maximum impeller eye area.

FIG. 28 INLET-VELOCITY TRIANGLE

angle at the hub will change from 48 to 44 deg for A , and from 33 to 34½ deg for B . The effect of such change on performance, if any, will be insignificant, but the method has the advantage of simplicity and a better theoretical reasoning.

The physical meaning of the ratio P_{12}/c_{m1} is the ratio of "shockless" capacity to the normal or design capacity Q_0/Q_n . The writer has shown in a previous publication⁸ that the best efficiency point always occurs at a capacity lower than the shockless capacity. The pattern of flow following from the described method of inlet-vane layout requires a constant angular velocity of prerotation at any capacity, which is the easiest thing to imagine and natural to expect.

It should be realized that the impeller-inlet conditions play only a minor part in comparison to the impeller discharge in locating the shockless and normal capacity of the pump.

A study of the discharge conditions from the impeller also is interesting and instructive. For this the writer has plotted the best efficiency points of the tests from Figs. 10 and 13, on the writer's chart of centrifugal-pump characteristics⁹ (Fig. 29 of this discussion). On this, heads and capacities appear in dimensionless form, (points E, F, G, H), and actual discharge-velocity triangles are obtained by joining these points with points A and O . All velocities appear on this chart as ratios to the impeller peripheral velocity at discharge. From inspection of this figure the following can be stated:

1 The points plot very closely on the respective lines of the discharge angle β_2 , the two high angle points fall slightly above

⁹ Ibid., footnote 1, p. 184.

FIG. 29 CENTRIFUGAL-PUMP CHARACTERISTICS

their respective lines. The latter could be expected as the performance of the author's pumps is better than those for which the chart was intended (best commercial pumps).

2 The absolute discharge velocity angle α_2' measures 13 deg. As far as can be ascertained from the small-scale drawings of the paper, the angle of the mean line of the diffuser vanes in B of Fig. 4 is approximately 13 deg.

3 Note that all points fall on the same line of c_2' (13 deg from the axis of heads), indicating that the peak-efficiency point is determined by the pump casing, which was the same for three impellers. If the casing were to be changed to suit the impeller-discharge angles, points would follow the constant specific-speed line, which is associated with a given impeller profile.

4 The absolute velocity at the impeller discharge for the point G (test Fig. 13) scales 0.525, which corresponds to $0.525 \times 146.3 = 76.8$ fps absolute velocity ($u_2 = 146.3$ is the peripheral velocity at discharge). The average velocity at the diffuser inlet is calculated to be $c_3 = 54.8$ fps. Some time ago the writer had prepared a curve, reproduced in Fig. 30 herewith, of what was called "volute velocity distribution factor" $c_3/c_2' = R_{c3}$. For the point G this factor is $54.8/76.8 = 0.713$ which falls on the curve in Fig. 30.

FIG. 30 VOLUTE VELOCITY-DISTRIBUTION FACTORS

The casing velocity-distribution factor represents the ratio of the average velocity in the volute or diffusion-vane casing to the maximum velocity at the impeller discharge. This latter is given approximately but very accurately by the writer's chart, Fig. 29.

The pump casing as finally adopted, with 6 vanes, was intended to provide mechanical strength to the casing and thus reduce its size and weight. Hydraulically the casing is equivalent to a double volute—with an addition of 4 guide vanes. With a diffusion angle of 40 deg in the radial plane (profile) and a small vane overlap, the 6-vane casing does not make a good diffuser.

The beneficial effect of the "rib" on the velocity distribution, Fig. 6(a), and efficiency, Fig. 7, can be observed on any double-volute pump as compared with single volute. In other words, hydraulically the 6-vane casing has no advantage over a double volute.

B. L. VANDERBOEGH.¹⁰ The extensive and painstaking research necessary to design pumps of this magnitude becomes evident when the testing-program results are released. The author is to be commended for his clear presentation of valuable data.

Comments by the author on several points would be enlightening. It would be interesting to compare tests made with the

¹⁰ Hydraulic Division, Newport News Shipbuilding and Dry Dock Company, Newport News, Va. Mem. ASME.

smooth pump casing with those of the segmented casing to learn of the degree of difference in frictional losses between the two.

It is noted the specifications permitted lengthening the pump-discharge nozzle beyond the original location, with a resulting gain in efficiency and head when pressure readings were taken farther downstream. This increased length was not allowed in testing the Granby pump models, and so, with due allowance for the difference in specific speeds and casing design, a comparison of test results is difficult. It is strongly urged that the recommendations of the Hydraulic Institute be followed in locating discharge piezometer connections. Pumps then would be allowed to develop their full heads and test results would be comparable.

In Fig. 6 of the paper the overlap of the diffuser vanes appears to be about 25 per cent of the vane length. This is a relatively short distance to allow for diffusion, and the reasoning that the water is more guided than diffused seems proper, for the figure also shows a rather rapid enlargement between vanes. Comments as to the percentage of velocity decrease in this diffusion area would be of interest.

It is noted in Fig. 16 of the paper that the point of discontinuity lies outside the operating range. This instability occurs at about 2 per cent above the high head condition and extends over a fairly broad range. A margin of 2 per cent appears relatively slight when it is considered that a surge of approximately 200 cfs is involved.

It is believed that data were taken well below the 270-ft head condition, but the H-Q test curves are not completely shown. Perhaps the author will describe the shape of the H-Q curve below 270 ft head and mention where cutoff occurred.

AUTHOR'S CLOSURE

The Bureau of Reclamation took an active part in the preliminary Grand Coulee model-testing program and also developed the first diffuser-type casing, so Mr. Winter's comments are therefore of particular interest and his discussion a valuable addition to this paper.

Mr. Winter suggests that a larger diffuser case with a greater diffuser expansion should reduce the unstable portion of the performance curve near the high-head condition shown in Fig. 3 of the paper. The author ran performance tests with the same impeller in two 6-vane diffuser cases, which had the same diffuser-vane entrance area but different ratio of the diffuser-vane inlet-to-outlet area. This ratio was 1.5 for a small case, the same as used in the final model for Grand Coulee, and 2.5 for a large case. The performance with the large case did not show any noticeable improvement in the unstable head-capacity range over the small case. The pump efficiency, however, as mentioned in the paper, was slightly higher for the pump with the large case than for the small case, and about equal to the pump efficiency obtained with the small case furnished with the separating rib. However, the weight of the large case was 25 per cent heavier than the small case.

The two types of diffuser-vane designs, investigated by Mr. Winter, to develop even pressure distribution around the impeller periphery have a great deal of merit. His reasoning, however, is based upon the assumption that the outlet velocity from the diffusers and the velocity in the volute sections are uniform. Actual measurements show uneven velocity distribution at the end of the volute discharge cone (see Fig. 8 of the paper), and the velocity distribution between the diffuser vanes shows a greater variation. It is therefore difficult to suggest a diffuser-vane design which will give balanced pressure distribution around the periphery before this uneven velocity type of flow has been further explored.

The effect of change of speed on the steepness of the performance curves, shown in Fig. 25 and Fig. 26, gives the mis-

leading impression that the slope of the performance curve could easily be changed. These curves are calculated from the same model performance by changing the size model ratio, which means operating the model at different speeds to meet the same operating point. This, in reality, is nothing more than moving the operating point up and down the same performance curve. The smaller pump at higher speed would move the operating point down on the performance curve and result in a steeper performance curve, but with reduced pump efficiency at the 310-ft operating point (see Fig. 16). A larger pump at lower speed would move the operating point up on the performance curve and improve the pump efficiency at the 310-ft operating point, but the high-head point would move closer to the unstable portion of the head-capacity curve.

The author agrees with Dr. Knapp that the Grand Coulee type diffuser casing has no hydraulic advantage over the double-volute case, but is hydraulically inferior. Unquestionably, the double-volute case will remain the practical and best solution in most pump designs, and the division line between it and the Grand Coulee type case will be determined by various factors, such as, size, test pressure, number of units involved, and others. Dr. Knapp's complimentary remarks, which clear up further some of the problems posed by the condition of operation of these pumps, are greatly appreciated.

Dr. Stepanoff shows a suction-vane layout, which has a better theoretical background than the one used by the author, if we suppose uniform radial velocity approach in the impeller eye at all capacities. In the design of entrance-velocity diagrams, consideration should be given to the uneven flow distribution in the impeller eye, which is of greater variation than measured at the suction flange, shown in Fig. 21 of the paper. The author agrees that the minor differences in vane angle arrived at by Stepanoff's and the author's procedure will have no significant effect on the performance.

The author feels gratified that the model-test results and pump proportions are in agreement with Stepanoff's excellent charts. The author objects to the quotation that the minimum suction-head requirements are obtained by using lowest practical impeller-vane inlet angles and maximum impeller-eye area. While the word, "practical" somewhat excuses the statement, it is well known to designers that the cavitation depends on the absolute inlet velocity which is the vector sum of peripheral and radial velocity, and that there is a ratio of these two velocities at which the cavitation will occur at the minimum head.

The pump casing as finally adopted is not equivalent to a double-volute case with additional guide vanes as claimed by Dr. Knapp and Dr. Stepanoff, but must be considered as a diffuser-type case with a dividing rib. The main purpose of a double-volute-case design is to balance the radial forces acting on the impeller, and therefore all volute sections 180 deg apart in a double-volute case are identical in area and shape. In the separating-rib-type case, however, the final volute sections 180 deg apart differ materially in shape with a half-circle shape in one, and a trapezoid shape in the other.

The last paragraph in Dr. Knapp's discussion is an excellent answer to Mr. VanderBoegh's remark regarding the length of the discharge cone. The author strongly supports Mr. VanderBoegh's recommendation that pump specifications should be based upon the Standards of the Hydraulic Institute and no deviations allowed.

The diffuser-vane length is determined by the chosen pump-case size or the ratio of diffuser-vane inlet-to-outlet area. A ratio of 1.5 was used in the diffuser-case design finally adopted, and the total diffuser-vane cone angle in the direction of flow was 12 deg, which is somewhat larger than the 8 deg recommended for uniform flow. In pump cases where the flow is far from uniform,

tests with cases having a total discharge-cone angle of 15 deg, have given the same pump efficiency as cases with 8 deg.

The instability in the head-capacity curve is admittedly close to the high-head operating point, but it is difficult to determine the percentage of safety required to guard against surges. The model development accomplished two major improvements in this respect: (1) It moved the unstable portion of the horsepower curve further away from the high-head point. (2) It eliminated the dip in the head-capacity curve, and thereby pre-

vented the pump from passing over a hump in the performance in case of a major surge.

Test data were taken for heads as low as 200 ft with 145 ft NPSH at the pump suction, and the head-capacity curve continued on the smooth curve without a sign of instability or cut-off.

In conclusion, the author wishes to thank the discussers for their encouraging comments and valuable contributions to this paper.

Heat-Conduction Errors in Temperature Measurements

By L. E. SMITH,¹ WATERBURY, CONN.

In practical applications of temperature measurements where the temperature-sensitive bulb assembly is fastened rigidly to a containing vessel, heat-conduction errors must be considered in order to determine the accuracy of the indicated or recorded temperature. This paper presents for various thermometer-bulb assemblies, the experimental magnitude of the heat-conduction error possible in a medium with a low heat-transfer coefficient (air), and in a medium with a high heat-transfer coefficient (water). The effect of heat-conduction error on the overall response in simulated practical installations is discussed. It is shown that comparative information on response action of any type of temperature-sensitive element necessitates careful considerations of the condition of attaching the element to a wall or vessel, where heat-conduction effects are present.

PRACTICAL CONSIDERATIONS

IN practical applications of temperature-measuring instruments, it is desirable that the temperature of the medium be indicated or recorded accurately and promptly, despite variations of the temperature outside the vessel containing the medium. In many applications, the measuring bulb, by means of a union connection, is fastened rigidly into a threaded bushing which is attached permanently to the containing wall. A supporting non-sensitive extension for the bulb usually separates the sensitive portion from the union connection, Fig. 1. For other applications, the bulb is inserted into a protecting well, Fig. 2, and for convenience of removal it is necessary that the bulb be smaller than the inside diameter of the well, resulting in an air gap between the bulb and the well. A liquid or metallic filler may be interposed between them, but in all cases, the transfer of heat from the medium to the sensitive portion of the bulb is retarded.

The primary requirement in measuring temperature is to transfer heat from the measured medium to the fluid inside of the sensitive portion of the bulb in the shortest possible time. It is also required that a minimum amount of the heat available from the measured medium must be lost to the union connection and vessel walls by way of the bulb extension. Where a well is used, the condition is aggravated because heat will also escape by way of that portion of the well which surrounds the bulb extension. The accuracy of measurement for a given application under a steady state of heat flow will be dependent upon the amount of heat lost to the union connection and the well head in a unit time. In the majority of cases, the temperature around the thermometer head will change with time, causing a change in the rate of heat loss. This change in heat flow will also influence the indicated temperature reading, an effect particularly emphasized in installations where the measured medium has a low heat-transfer

FIG. 1 UNION-CONNECTED BULB

FIG. 2 VARIOUS WELLS USED WITH UNION-CONNECTED BULBS

value, such as flowing gas or air. Here, too, the over-all rate of response of the thermometer bulb will be seriously affected.

Others have written papers on response characteristics of thermometer elements (1, 2, 3)² and heat-conduction effects (4, 5). The object of this paper is to present experimental data simulating practical applications, to indicate the magnitude of heat-conduction errors, and to show how heat conduction influences the response time of thermometer bulbs. Means for improving the over-all performance of an installation are studied. Filled-system thermometer assemblies are utilized in this investigation, but similar results will be obtained with resistance-bulb or thermocouple assemblies.

TEST EQUIPMENT

The thermometer system used in the tests was liquid-filled, and consisted of a union-connected bulb, Fig. 1, which was connected to the recording Bourdon-spring element by 10 feet of capillary tubing. The spring element was installed in a regular recording-thermometer case, and readings recorded on a 12-in.-diam chart driven by a clock mechanism. This system was of the fully compensated variety, so that changes in ambient temperature of the capillary tubing or spring element had no effect on the recorded reading.

In the case of the union-connected bulb with bushing, all heat-conduction loss is through the extension, and the factors which affect the rate of heat loss from the sensitive portion of the bulb to the head and bushing for a given application are as follows:

FIG. 3 HEAT-CONDUCTION APPARATUS INSTALLED IN AIR BATH

(a) The thermal conductivity of the material of the extension; (b) the cross-sectional area of the extension; (c) the length of the extension. In the tests, the following combinations of bulb and extension were used (extension was $1\frac{1}{2}$ in. long in all cases; see Fig. 1, for actual dimensions):

- 1 Copper bulb, with $\frac{1}{4}$ -in-OD \times 0.155-in-ID copper extension.
- 2 18-8 stainless-steel bulb, with $\frac{1}{4}$ -in-OD \times 0.155-in-ID 18-8 stainless-steel extension.
- 3 18-8 stainless-steel bulb, with $\frac{1}{8}$ -in-OD \times $\frac{1}{16}$ -in-ID 18-8 stainless-steel extension.

When the bulb is installed in a well, the heat loss is the total through the portion of well surrounding the extension, and that through the extension. The design factors which affect the rate of heat loss from the body of the well surrounding the sensitive portion of the bulb are the same as for the bulb extension. In the design of the well it is possible to increase the external area of the surface exposed to the medium to improve the rate of heat flow. The following combinations were used to determine the effect of the various factors (see Fig. 2 for well designs):

- 1 Copper bulb with $\frac{1}{4}$ -in-OD \times 0.155-in-ID copper extension in (a) a finned aluminum well with 0.142-in. wall; (b) a finned 18-8 stainless-steel well with 0.142-in. wall.
- 2 18-8 stainless-steel bulb with $\frac{1}{4}$ -in-OD \times 0.155-in-ID 18-8 stainless-steel extension in (a) a finned aluminum well with 0.142-in. wall; (b) a plain aluminum well with 0.142-in. wall; (c) a plain aluminum well with 0.045-in. wall; (d) a finned 18-8 stainless-steel well with 0.142-in. wall; (e) a plain 18-8 stainless-steel well with 0.142-in. wall; (f) a plain 18-8 stainless-steel well with 0.045-in. wall.
- 3 18-8 stainless-steel bulb with $\frac{1}{8}$ -in-OD \times $\frac{1}{16}$ -in-ID 18-8 stainless-steel extension in (a) a finned aluminum well with 0.142-in. wall; (b) a plain aluminum well with 0.142-in. wall; (c) a finned 18-8 stainless-steel well with 0.142-in. wall; (d) a plain 18-8 stainless-steel well with 0.142-in. wall; (e) a plain 18-8 stainless-steel well with 0.045-in. wall.

The heat-conduction apparatus used to determine the performance of the bulb and well assemblies is shown in Fig. 3. It consists essentially of a copper plate provided with a pipe thread for holding the well or the bushing for the union-connected bulb. A

thermocouple was imbedded in the copper plate, the temperature of which was recorded continuously and controlled by a recording-potentiometer input controller. Heat was supplied by a resistance coil, and the temperature of the plate was varied by adjusting the set point of the controller. The plate-and-coil assembly was fastened rigidly inside of a monel tank. The complete unit could be handled easily and moved from one water bath to another, or quickly placed in the air chamber, as shown in Fig. 3.

The air chamber was used for studying response action and heat-conduction errors of the various thermometer-bulb assemblies in a flowing air medium. It consisted of a long piece of brass pipe connected rigidly to an upper chamber which housed the heat-conduction apparatus. The air chamber was heated to a constant temperature by first passing the air through $\frac{3}{16}$ -in.-diam coiled copper tubing submerged in a controlled water bath and then bleeding it into the chamber through a number of small holes in the tubing. The flow rate was controlled by measuring the pressure drop across a calibrated orifice, and the velocity of air past the inserted bulb or well in the chamber was calculated.

Air chambers were installed in each of two adjacent water baths, one bath being held at 70 F, the second bath at 120 F.

EXPERIMENTAL PROCEDURE

The tests were conducted in water, a medium with high heat-transfer coefficient, and air, a medium with low heat-transfer coefficient. In the water-medium tests, the heat-conduction apparatus was placed in the cold bath with the monel tank partly submerged. Sufficient time was allowed for the heat-conduction plate and bulb to reach their equilibrium temperature conditions. The apparatus was then transferred quickly to the hot bath, and equilibrium conditions again reached. Time-temperature curves of the bulb-assembly response were obtained on the recording thermometer, and similar curves for the copper conduction plate were obtained on the recording-potentiometer controller. The temperature of the heat-conduction plate was then raised about 50 deg F by connecting the heating unit to the controller, and equilibrium conditions were again reached. The recorded change in the temperature of the bulb assembly was noted for the temperature change of the heat-conduction plate. The change in bulb temperature due to 1 deg change in plate temperature is called the "extension conduction error," a term which will be used throughout this paper.

In the air-medium tests, the heat-conduction-plate apparatus with bulb assembly, installed in the air-chamber unit, was located in the cold-water bath. Response of the bulb assembly in air at a given velocity was determined by transferring the heat-con-

duction-plate apparatus from the cold-air chamber to the hot-air chamber. The procedure was identical with that in the water-bath tests, except that the temperature of the heat-conduction plate was raised in 20 F intervals to provide additional points on the extension conduction-error curve.

In addition to the foregoing tests, the response of the various bulb and well combinations in the water bath and air bath was obtained in the usual way without the heat-conduction apparatus, that is, by moving the unattached bulb assembly from one bath to the other. In the air bath, a third method of obtaining response was utilized. The heat-conduction plate was heated up to the hot-air temperature prior to the insertion of the heat-conduction apparatus from the cold-air chamber to the hot-air chamber. It remained in the cold-air chamber until temperature equilibrium was obtained. Extension conduction effect on the response action was thus obtained from heat flowing into the sensitive portion of the bulb.

DATA DERIVED FROM TESTS

Water-Bath Tests. The response time for a 63.2 per cent change (1) (called time constant or time lag), a 90 per cent change, and the heat-conduction factor are tabulated in Table 1 for an agi-

TABLE 1 PERFORMANCE OF UNION-CONNECTED BULB ASSEMBLIES IN AGITATED WATER*

* $\frac{1}{4}$ -in.-OD \times 0.155-in.-ID stainless-steel extension.

tated water-bath medium. The complete response actions of the bare bulb and the various bulb and well combinations are shown in Fig. 4. It should be noted that data include tests made both with the assembly attached and not attached to the heat-conduction plate. In all these tests a stainless-steel bulb with a $\frac{1}{4}$ -in.-OD \times 0.155-in.-ID stainless-steel extension was used.

It is seen that with a bulb assembly immersed in a fluid with a high heat-transfer coefficient such as water:

- 1 The heat-conduction plate has no effect on the response of

FIG. 4 RESPONSE IN WATER WITH AND WITHOUT HEAT-CONDUCTION APPARATUS

the union-connected bulb assembly with bushing whose extension-conduction error was very low.

2 The heat-conduction plate has only a small effect on the response of the union-connected bulb assembly with well. The response action is slowed down about 10 per cent when the heat-conduction apparatus is used.

3 The material of the well has some effect on the response, the response depending upon the thermal conductivity and heat capacity of the well material.

4 The use of fins on a well, as applied and designed here, does not improve the response or materially affect the conduction error.

5 The use of a well produces an extension conduction error which is practically independent of the material of the well.

6 Extension conduction errors are negligible for a bulb with a stainless-steel extension immersion of $1\frac{1}{2}$ in. installed in a bushing.

In order to check the extension conduction effects obtained with the heat-conduction apparatus, a separate installation was made by inserting the well in a bushing welded into the sheet-metal side of the water bath used for the tests. With the bulb installed in any of the listed wells, the recorded reading after equilibrium conditions were obtained was $\frac{3}{4}$ F lower than the reading with the bulb suspended at the same position in the bath, but not rigidly connected to the metal side. The temperature of the exposed head of the well was 105 F, while the water bath itself was 120 F. This gave an extension conduction error of 0.05, which agreed with the results obtained with the heat-conduction apparatus.

It is thus apparent that even in the best of heat-transfer media, the bulb assemblies must be considered carefully. In applications where the length of the extension is shorter, the cross-sectional area of the extension is greater, or the extension material has a higher heat conductivity than the design tested, the extension conduction error will be greatly increased. This condition will be greatly aggravated in poor heat-transfer media, as shown in the following discussion on results in the air bath.

FIG. 5 EXTENSION CONDUCTION ERROR OF VARIOUS UNION-CONNECTED BULB ASSEMBLIES WITH BUSHING AND WITH WELLS (Air velocity, 250 fpm.)

FIG. 6 EFFECT OF FINES ON WELL AND OF WELL THICKNESS (Air velocity, 250 fpm.)

Air Bath Tests. The extension conduction errors obtained with different union-connected bulb assemblies and varying plate temperatures are shown in Fig. 5, for an air velocity of 250 fpm. The relationship between plate temperature and extension conduction error is found to be linear. The following conclusions are possible for the various bulb assemblies with well:

1 The worst combination is a bulb with a good conducting extension (copper) and a good conducting well (aluminum). A 1.7 F change in the plate temperature causes a 1 F change in bulb reading, or 0.59 extension conduction error.

2 If the well material only is changed to a less conducting material (stainless steel) a small improvement is noted; 0.50 extension conduction error.

3 If the extension material is changed to a less conducting material, the improvement is more marked; 0.37 extension conduction error.

4 If both the extension and well materials are changed to less conducting materials, the improvement is outstanding, with the extension conduction error decreased to 0.11. This combination would be a desirable one for practical installations.

In considering bulb assemblies with bushing, in which the bulb is directly exposed to the air medium, the following is observed from Fig. 5:

1 With the $\frac{1}{8}$ -in. copper extension, the extension conduction error is 0.17. Thus this bulb alone produces a greater error than that obtained with the best bulb assembly with well combination in item 4 of the foregoing conclusions.

2 If the extension is changed to $\frac{1}{8}$ -in. stainless steel, the extension conduction error is decreased to 0.071.

3 If the cross-sectional area of the stainless-steel extension is decreased by use of $\frac{1}{8}$ -in-OD \times $\frac{1}{16}$ -in-ID instead of $\frac{1}{8}$ -in-OD \times 0.155-in-ID material (area ratios of 1 to 3), the extension conduction error can be reduced to 0.043.

A series of tests were made on wells to study the effect of fins, and also of the thickness of the well wall on the extension con-

Fig. 7 RESPONSE OF UNION-CONNECTED BULB ASSEMBLY WITH BUSHING AND WITH WELL ATTACHED TO HEAT-CONDUCTION APPARATUS

duction errors (see Fig. 6, for data.). The following conclusions can be made:

1 Removal of the fins from the well increases the extension conduction error. In the case of the aluminum well, the extension conduction error is increased from 0.33 to 0.50; for the stainless-steel well, from 0.083 to 0.132.

2 A decrease in the wall thickness of the stainless-steel well from 0.142 to 0.045 in. decreased the extension conduction error from 0.132 to 0.091.

It should be mentioned that a change in the cross-sectional area of the stainless-steel extension from $\frac{1}{8}$ -in.-OD \times 0.155 in. ID to $\frac{1}{8}$ -in.-OD \times $\frac{1}{16}$ -in.-ID produces a decrease in the extension-conduction error from 0.11 to 0.083, when the bulb is used with the stainless-steel finned well.

Response in Air. In Fig. 7 the response of the union-connected bulb assembly with bushing and wells is shown. A bulb extension of $\frac{1}{8}$ -in.-OD \times $\frac{1}{16}$ -in.-ID stainless-steel material was used in all cases. The actual temperature of the heat-conduction-apparatus plate is also plotted with time for the given response runs. In this part of the test, the plate was allowed to heat up from the natural flow of heat from the well and bulb.

In Table 2, data taken from Fig. 7, are tabulated. Also shown is the 90 per cent response time of the same assemblies obtained with the heat-conduction-apparatus plate heated initially to the temperature of the hotter air bath before beginning the response test, and with the bulb assembly being moved from one chamber to the other without the use of the heat-conduction-apparatus plate.

From Fig. 7 and Table 2 it is seen that:

1 The less the extension conduction error, the better is the response action.

2 The greater the extension conduction error, the faster does the heat-conduction-apparatus plate heat up. This is to be expected, as more heat flows up the well wall and the extension per unit time.

3 The response of a bulb assembly when immersed directly from one bath to another is much better where heat conduction can be disregarded than where heat conduction can function. The divergence between the two methods of obtaining response action is more marked for a poorly designed bulb assembly.

CONCLUSION

This paper has attempted to show the advisability and the necessity of considering the complete design of any type of a tem-

NOTE: Under heat-conduction apparatus, "Yes—heated" refers to the condition where the conduction apparatus was heated before moving the assembly from the cold bath to the hot bath.

perature-measuring bulb from the viewpoint of extension conduction errors, rather than from the response action of a bulb or bulb-and-well combination, as ordinarily obtained by simply moving the bulb or bulb assembly from one bath to another.

In the case of a measured medium with a good heat-transfer coefficient, this common way of obtaining the response characteristic is generally acceptable. However, designs are possible where there may be considerable heat transfer, resulting in large extension conduction errors. This is true in a design with no extension between the sensitive portion of the bulb and the union connection, or where a short extension has a large cross-sectional area and is composed of a good heat-conducting material.

In a poor heat-transfer medium, the usual way of obtaining the response characteristic is not advisable, unless one knows that heat-conduction effects are negligible. Extension conduction errors may be very large in many industrial applications, particularly where it is necessary to use a protecting well. Comparative response actions in practical applications may be entirely different from those obtained by the customary laboratory methods.

In general, it is recognized that the lowest extension-conduction error can be realized by the proper selection of material, a minimum cross-sectional area of the well and the connecting extension of the bulb, and a maximum length of the extension between the sensitive portion of the bulb and the union connection to the well.

Too often, a thermometer system is condemned as having calibration error, or not being properly compensated for ambient-temperature changes. This observation may be based upon a check with a mercury-in-glass test thermometer placed in another well with an extension conduction error which may be much differ-

ent from that of the recording thermometer bulb-and-well installation. The discrepancy noted may be the result of extension conduction errors, and will vary with the ambient temperature. On the other hand, an agreement between the mercury-in-glass thermometer and the tested thermometer system does not necessarily mean accurate calibration, as they may possess similar extension conduction errors. It is necessary to know the magnitude of the extension conduction error of the test thermometer in order to determine the exact performance of the measuring-thermometer system.

The best way to overcome the effects of heat conduction is the familiar method of covering the thermometer head and its containing vessel with insulation so that the head remains at the approximate temperature of the measured medium and will not change measurably with ambient-temperature changes.

This paper has touched upon the high lights of the variables which result in heat-conduction losses, and has not attempted to consider errors due to other effects such as radiation. Such errors

would be added to those from heat conduction to give the over-all errors. Also statements made are based upon a given immersion assembly; for a different immersion, the relative performance may be altered.

Fatigue Tests on Flanged Assemblies

By A. R. C. MARKL¹ AND H. H. GEORGE,² LOUISVILLE, KY.

Qualitative differences between the various types of pipe flanges in common use have long been recognized, but their quantitative evaluation in terms of rules, formulas, or ratings which could be used as a guide by the practicing engineer has been accomplished only partially. Two problems are involved, i.e., the determination of the strength and tightness of a flanged assembly under internal pressure, and the other the effects of the variable bending moments associated with mechanical vibrations or temperature fluctuations of the flowing medium or surrounding atmosphere. The present investigation is intended to contribute toward an understanding of the latter phase; stress-intensification factors are reported which have been obtained from fatigue tests of full-scale assemblies of 4-in. flanges of the 300-lb ASA pressure class and hence are directly applicable to piping flexibility calculations.

INTRODUCTION

OF LATE, a growing demand for a more complete understanding and detailed evaluation of the components entering into the design of pressure containers and piping has made itself felt. In the pressure-vessel field, this has led to the formation of the Pressure Vessel Research Council which already has produced valuable information on the magnitude of local stresses at shell-to-head junctions and other related problems. In the piping field, evidence of the same trend is to be found in the efforts of a special subgroup of Subcommittee 3 of ASA Sectional Committee B16 to define more closely the limitations of the commonly used types of pipe flanges and to differentiate between their pressure ratings.

The pressure-vessel flange problem is primarily one of statics and involves an evaluation of the interaction of bolt extension, gasket compression, and flange rotation under the effects of an applied bolt load and internal pressure, as it affects flange stress and, perhaps more significantly, joint tightness. For flanges forming part of a piping system, an additional, dynamic problem arises, namely, that of evaluating the useful life of assemblies subject to cyclic bending moments caused by mechanical vibrations or thermal changes.

SCOPE OF TESTS

The investigation reported herein relates to the latter aspect of the problem. While it has been initiated with the express purpose of assisting ASA Committee B16 in its difficult task of defining the proper uses, ratings, and limitations of different flange types, at the same time it is to be considered as part of a comprehensive fatigue-testing program on full-scale piping assemblies undertaken by the authors' company as a service to the industries which use its products.

Cyclically reversed bending tests were carried out on assemblies involving the following types of commonly used flanges:

- (A) Slip-on flanges.
- (B) Socket-welding flanges.
- (C) Welding-neck or butt-welding flanges.
- (D) Ring flanges.
- (E) Lap-joint flanges.
- (F) Threaded flanges.

Wherever different methods of attachment could be visualized, their influence on the life of the assembly was explored separately. For instance, in the case of slip-on flanges, not only were two types of double-welded designs tested, but separate runs were made with a hub weld only and a face weld only, to determine their relative contributions to the endurance strength of the assembly. In the case of socket welding flanges, similar investigations were carried out and, in addition, an attempt was made to evaluate the effect of the relative proximity of front and back welds; also to find out whether any significant differences in strength are evident where the pipe is butted against the bottom of the socket as compared with a loose assembly leaving a gap at the end of the pipe. In the case of threaded flanges, some assemblies were made up with normal thread engagement, and others with the pipe threaded through the flange and refaced. Every one of the basic variants is illustrated in Fig. 1.

All the assemblies involved in the main test series were made using 4-in. carbon-steel flanges of the 300-lb ASA pressure class and standard weight (Schedule 40) pipe, all welding being done by the Heat and Power Corporation, Baltimore, Md., employing welders qualified by The Hartford Inspection and Insurance Company.

Supplementary tests were run with some of the same types of assemblies, but using ordinary experienced welders who had been instructed expressly to deposit the minimum amount of welding which might be considered as passing the requirements of Section VIII of the ASME Boiler Construction Code, the express purpose being to widen the range of the test data and assure that any values derived for design use would be reasonably conservative.

A further supplementary test series, restricted to slip-on and welding neck flanges, was run with pipe of 0.080 in. wall thickness to obtain an idea of the size effect; this test series, besides providing direct information on assemblies involving 4-in. light-wall pipe, also might be considered as a model test of, say, a 12-in. flange attached to standard-weight pipe.

MATERIALS AND PREPARATION

All assemblies were of 4-in. nominal size, the flanges being made of forged steel and conforming to the 300-lb American Standard, and the pipe and lap-joint stub ends to standard weight (except for the supplementary tests on lightweight pipe referred to previously). Dimensional and materials information on these components is compiled in Table 1.

Through-threaded bolt studs of $\frac{1}{4}$ in. diam and SAE 4140 material were used to attach the test flanges to the mating flanges on the adapters, which were designed to be slightly stiffer to assure that flange failure, if encountered, would occur in the test specimen rather than the adapter. The physical properties of the studs conformed to the requirements of ASTM Specification A193, Grade BC. The semifinished hexagon nuts conformed to the heavy series of ASA Standard B18.2.

Gaskets were $\frac{1}{16}$ in. thick \times 4 in. ID \times $7\frac{1}{4}$ in. OD asbestos

FIG. 1 DETAILS OF FLANGES AND VARIANTS OF FLANGE ATTACHMENT TESTED IN MAIN SERIES

The hub welds were specified to be $\frac{3}{16}$ -in. leg size or approximately 15 per cent heavier than required by the Code for Pressure Piping; the deposited welds actually ranged from $\frac{1}{4}$ to $\frac{11}{16}$ in. Symbol r denotes weld deposited against a $52\frac{1}{2}$ -deg recess, while symbol f denotes an ordinary fillet weld. The end welds for the slip-on flanges were full-fillet welds, the dimension e from the end of the pipe to the flange face being held to approximately $\frac{3}{8}$ in. The values i and p marked opposite each variant, respectively, denote the stress intensification factor and percentage of fatigue life in terms of that of straight pipe. The values noted opposite B1, B3, and F represent averages, weighted by the number of tests, of the subvariants shown thereunder.)

^a The ring flanges were machined from forged flanges.

composition, manufacturer's designation "Tenax." A new gasket was used for each assembly; it was applied dry, without prior wetting or the use of a gasket compound.

The welds made in joining certain flange types, notably the slip-on and socket welding variants, were of two markedly different qualities. All the welding for the main test series was carried out by ASME Code qualified welders; while not strictly code welds (since they were not code-inspected or chipped to the extent customary when preparing for code inspection), the welds may be considered representative of good commercial practice; they were generously proportioned (the fillets attaching the flange hubs were practically full size) and presented a smooth, somewhat concave contour. By contrast, the welds prepared by welders of the research department of the authors' company for the supplementary tests, which were meant to represent the least weld size and quality compatible with code requirements, were small (the weld size on hub fillets was of the order of $\frac{5}{16}$ in. to $\frac{3}{8}$ in.) and of a beadlike, unfinished appearance.

Incidentally, no difficulties were encountered by the fabricator's welders in welding any of the flange types, except that the face welds on slip-on flanges were found to chill rather quickly,

resulting in an occasional poor weld which had to be machined out and redone.

The threaded flanges were made up with machine-threaded pipe to ASA Standard B2.1. In one set of tests, they were pulled up with 2000 ft-lb torque for normal thread engagement; in the second set, where the pipe was threaded through the flange and refaced, a 4000 ft-lb torque was applied. A liquid thread compound, sold under the name "Copaltite," was used on the threads in both cases.

TEST EQUIPMENT

A specially designed fatigue testing machine of the specific-strain reversed-bending type, as described in an earlier paper by the senior author,³ and illustrated in Fig. 2, was used. The test principle is a simple one, as becomes evident from the diagram in Fig. 3; the assembly presents a cantilever beam fixed at one end, with a cyclically reversed load being applied at the other. The specimen proper is located close to the fixed end, where the bend-

FIG. 2 FATIGUE-TESTING MACHINE

FIG. 3 DIAGRAM OF TEST ASSEMBLY

ing moment is a maximum. In the main test series, an adapter was used to approach the condition of two mating flanges of equal stiffness; in the supplementary tests no adapter was used, the test flanges being bolted directly to the anchor plate.

TEST PROCEDURE

Prior to mounting the specimens, each assembly was inspected and subjected to a pressure test of 600 psi, which is the service pressure at atmospheric temperature set up in ASA Standard B16e for flanges of the 300-lb-pressure class. Leakage was encountered in a single instance, this being a slip-on flange attached by a face weld only; the defective fillet was machined out, the specimen rewelded and retested with satisfactory results.

In mounting the specimens, careful attention was given to alignment and uniformity of bolt pull-up. The $\frac{3}{4}$ -in. bolts were pulled up incrementally with a torque wrench, using a predetermined sequence. The torque was set at 2000 in-lb, which corresponds to approximately 40,000 psi bolt stress, as determined with SR-4 strain gages. Originally it was planned to apply only 1200 in-lb, but this led to early gasket leakage of the specimens subjected to high deflections.

In the next step, each specimen was cycled at a low deflection amplitude about 20 times to "iron out" mounting irregularities; specimens were then realigned, where necessary, and the bolts rechecked with the torque wrench.

A load-deflection calibration of each specimen was next carried out, and the results were plotted as curves; the variation between individual specimens belonging to any one series being of the order of only a few per cent, an average or typical curve, such as is plotted in Fig. 4 for the welding neck type, was considered as adequate for all tests of one type. Using these data and the anticipated stress intensification factors, amplitudes of deflection were selected so as to spread failures evenly within the range from 1000 to 1,000,000 cycles.

Some of the large displacements required for the short-life

FIG. 4 TYPICAL LOAD-DEFLECTION CALIBRATION CURVE FOR WELDING-NECK FLANGE ASSEMBLIES

(Note that yielding occurs at appreciably higher load in the repeat calibration as compared with the first load application. The value S used in plotting the $S-N$ curves, Figs. 7, 8, and 9, is based upon the dash-dot extrapolation of the straight portion of the calibration curve.)

specimens fall onto the curved part of the load-deflection curve, denoting a stress high enough to produce more than local yielding. In the conversion of these displacements into loads, moments, and ultimately, stresses, the load-deflection curve, however, was considered as a straight line, i.e., the loads in the yield zone were obtained by an extrapolation from the elastic zone. A justification of this procedure, which, while not strictly correct, offers practical advantages, is given later under "Numerical Evaluation of Test Results."

In order to ascertain whether the originally applied load was maintained throughout the cyclic tests, a representative number of tests were interrupted for making check determinations of the load-deflection ratio. On flanges with wide gasket faces, no change in flexibility could be detected as the fatigue test progressed, and hence the stress conditions could be assumed as constant. The same was not true of the lap-joint flanges, specifically those under a high load. For example, in one specimen subjected to a load of 2350 lb (corresponding to failure in less than 3000 cycles), the load was reduced by about 3 per cent at 40 per cent of the total life of the assembly, by 10 per cent at 60 per cent, and by 16 per cent at 80 per cent of the life. After the stub end had cracked, the load was found to be 20 per cent lower than that originally applied. Inspection after disassembly led to the definite conclusion that the loss in load was attributable to progressive destruction of the gasket; the tops and bottoms at the inner circumference, which were alternately subjected to very high and low compressive stresses, were badly "chewed up." This was not the case for the lap-joint assemblies subjected to low moments, nor for any of the other assemblies, the gaskets invariably being found in good usable condition on taking the flange apart after failure.

All specimens were filled with water; a 25-in. head was held on those not under pressure to serve as a means for recognizing failure promptly. In order to find out whether the face weld cracked before the hub weld in double-welded slip-on or socket welding assemblies, a $\frac{1}{8}$ -in. hole was drilled through the hub at an angle of 45 deg from the bottom.

After all preliminaries were completed, the machine was started up and kept under constant observation. Where leakage appeared (or, in rare instances, a crack was noted shortly before leakage became apparent), the cycles which the unit had run were recorded. However, the test in nearly all cases was continued for at least 20 per cent more cycles to confirm failure and give information on the direction of crack propagation. Tests where no failure occurred within one or two million cycles were abandoned. In the case of threaded flanges, a slight seepage

along the threads, unaccompanied by a crack, often became evident early in the tests; by comparison, the later actual failure of threaded assemblies was always heralded by a sudden flow.

After completion of the test, the specimen was removed and photographed; a quarter section was cut out, with one of the saw cuts going through the center of the initial crack, and this was then etched and photomicrographed to record the type and location of failure. An occasional micrograph was made for more detailed study.

VISUAL TEST EVIDENCE

For various types of bolted flanged connections, tested with a given gasket and a uniform bolt pull-up, the tests established what type of failure is encountered under conditions of cyclic bending, where it occurs, and how many reversals are necessary to bring it about.

A joint could be rendered unsatisfactory by the occurrence of either of two things, i.e., it could leak, or some component could break. Leakage across the gasket to the outside of the flange or through the bolt holes did not occur in a single instance under the test conditions. A possibility of such leakage was approached, however, in the case of lap-joint assemblies where alternating overcompression of the gasket and release of most of its load resulted in deterioration of a large part of the gasket area in contact with the lap face. Another type of leakage, in the form of a persistent seepage along the threads, was encountered with threaded flanges. Even with only 25 in. head of water, this occurred long before structural failure, and with 600 psi pressure and some of the higher bending moments, around 100 reversals were enough to start a dribble of water.

In general, apart from the threaded joints, the usefulness of all

flange types was terminated by structural failure, not of the flange proper or the bolts, but invariably of the pipe, or, where a single attachment weld of small cross section or poor contour was used, the weld. All of these failures occurred as circumferential cracks and started on the outside of the pipe at or near the top or bottom of the assembly where bending stresses were highest. Fig. 5, reproducing representative photomicrographs taken of failed specimens of the main test series, will be used to comment more in detail on the nature of the failures.

The top line in Fig. 5 shows variants of slip-on flange attachment in the order of decreasing strength; the first three photographs, identification A1, A2, and A3, reveal identical failures, at the toe of the hub weld, whether a face weld was used in addition to it or not, and whether the hub weld was deposited against a square hub face or a reverse bevel or recess. In the last photograph, identification A4, which represents the obviously weak and hence unusual construction, where a face weld only is applied, failure occurred across the throat of the fillet weld. The middle line of photographs, in which the four basic variants of socket-welding flange attachment are assembled, presents almost identical evidence and requires no individual comment.

Referring to the bottom line, the butt-welding flange, shown at the left, designation C, shows failure at the edge of the weld overlay away from the flange, the crack remaining entirely within the pipe, as is also evident from the photomicrograph in Fig. 6. This is typical also of the cracks at the toes of fillet welds. The ring flange, designation D, failed at the extreme edge of the weld, as in the case of hub welds of slip-on or socket welding flanges. The lap-joint assembly, designation E, cracked across the stub end, close to the tangent point with the fillet radius. The threaded flange, designation F2 (and likewise F1, which is not shown)

FIG. 6 PHOTOMACROGRAPH AND PHOTOMICROGRAPH OF CRACK IN WELDING NECK FLANGE ASSEMBLY
(Micrograph covers circled— $1/8$ -in. actual diam.—area of macrograph. Crack starts in edge of weld and propagates through pipe. Fracture is cross-crystalline.)

cracked through the root of one of the first three engaged threads.

Of the two supplementary series, the few exploratory runs of butt welding and double-welded slip-on flanges with lightweight pipe gave the same kinds of failure as the main test series. The other series, in which small and poorly contoured welds were used with standard-weight pipe, differed in only one respect; where flanges were attached by a single fillet weld at the hub, the weld itself failed in three out of four specimens.

The following conclusions can be drawn from visual observation during and after test:

1 Flanges of the size and types investigated, with the given gasket material and size, and using an amount of bolt pull-up in line with common practice, are stiff enough to avoid leakage across the gasket and strong enough to prevent failure of the flange proper under its maximum rated service pressure and a superimposed bending stress of appreciable magnitude.

2 The welds customarily deposited by experienced welders are more than adequate to prevent failure of welded joints, this being true even of single-fillet welded construction; not included in this statement, however, are slip-on and socket welding flanges with weld attachment of the pipe end only, these constructions not being found in common usage.

3 Caution is in order when using lap-joint flanges with laps of a thickness of the same order as the pipe wall in locations of high bending moments, since the lap apparently rocks back and forth on the gasket, and tends to destroy it.

4 Threaded flanges are unsatisfactory for any but the mildest cyclic services; the threads constitute not only a structural weakness, but are prone to open up under bending and cause leakage.

5 Structural failure appears associated entirely with contour, the crack invariably appearing at a location of marked change in section adjacent to the flange. For welded joints, this is the edge of the weld, for lap joints the start of the fillet, and for threaded joints the notch formed by the root of the thread.

NUMERICAL EVALUATION OF RESULTS

Fatigue data are usually reported in the form of so-called $S-N$ curves, and where the tests performed involve a comparison of a part in which a stress raiser is present with a similar part with undisturbed stress flow, it is convenient to interpret the results in terms of a stress-intensification factor.

For practical piping design, the properties of straight pipe offer the most satisfactory reference medium, since the bulk of piping is straight pipe. For this reason, the endurance strength of an assembly, involving a flange and straight pipe of a certain size and wall thickness, will herein be referred to the endurance strength of the same kind of straight pipe by itself. In an earlier paper by

the senior author,³ the endurance strength S of commercial straight Grade B carbon steel pipe between limits of 500 to 500,000 cycles of stress reversal was tentatively expressed in terms of cycles-to-failure N by the equation⁴

$$S = 245,000 N^{-0.2} \dots \dots \dots [1]$$

To make possible the construction of an $S-N$ curve for the recording of the present tests, it becomes necessary to translate the applied deflections into nominal stresses. In so far as the stresses caused by the deflections imposed upon the test cantilever remain within the elastic limit, the load-deflection calibrations of the different assemblies made preparatory to these tests serve to establish the loads corresponding to any specific deflection; by multiplication by the lever arm from the point of load application to the point of starting failure, the controlling moment is obtained, and this, divided by the section modulus of the pipe used, gives the nominal stress. In the present tests, however, the larger displacements applied in the short-life runs definitely caused more than local yielding. It would have been entirely possible to establish the corresponding load, and therewith the stresses, from the applicable load-deflection curve. However, in view of the fact that the results of this investigation are primarily intended for use in the flexibility analysis of piping systems (where the displacement is given and the loads or reactions are solved for), and since such calculations are commonly based upon the elastic theory, it has been considered preferable to extrapolate the straight-line portion of the load-deflection curves (see Fig. 4 for an example) and plot the cycles-to-failure against a fictitious stress thus obtained, which, obviously, is higher than the actual stress.

This last is the basis upon which the median lines given as the $S-N$ curves for different assemblies in Figs. 7, 8, and 9, have been derived. They are all drawn parallel to the $S-N$ curve for straight pipe expressed by Equation [1] and go through the computed center of the respective group of test points obtained from the main series; the results of the supplementary tests series (shown by symbols of reduced size, but otherwise identical with those used for recording the results of the main tests) have been ignored in drawing the median lines. The justification for using a constant slope for all median lines resides in the advantage this offers of representing the stress-intensification factor as a constant, which would not otherwise be possible. A study of the charts indicates that this arbitrary adjustment is accomplished without violating the test evidence seriously. To avoid undue reliance on the median lines in the low-cycle range, in view of the liberties taken in extrapolating the load-deflection curve beyond the elastic range, these median lines have been cut short at a stress level roughly corresponding to definite yielding.⁵

The test results as reduced to these median lines are readily interpreted in either of two ways. To derive the stress intensification factor i for any particular assembly, the nominal stresses applicable to straight pipe and the assembly in question are read at the intercepts of the two corresponding median lines with any one ordinate, and these divided by each other. To determine the comparable life of any assembly in relation to that of straight

⁴ Results obtained by this formula should not be confused with results of fatigue tests on polished bars, since commercial straight pipe involves certain inherent stress raisers in its surface condition, and additional stress raisers are introduced by any form of clamping or joining, mechanical or by welding, regardless of the amount of care taken to avoid notch effects. This should be well understood in view of possible future attempts at a rigorous mathematical analysis of the shapes involved in the present test.

⁵ It will be noted by reference to Fig. 4 that the departure from a straight-line law occurred much earlier in the first load application, as compared with subsequent retests; the latter only have been considered significant in the present investigation.

		6	2.83 ^b	0.6 ^b						

^a Value corrected for loss in load observed during course of test.

^b Value based upon first appearance of seepage whether accompanied by crack or not (i here is not strictly a stress-intensification factor, but may be applied as such for design purposes).

i = stress intensification relative to straight pipe.

p = life of assembly relative to straight pipe.

pipe, the cycles-to-failure are read for the assembly in question and for straight pipe along any abscissa denoting constant nominal stress, and the one is then expressed as a percentage p of the other. Both the i and p values for all variants tested in the main series are recorded against each type in Fig. 1 and compiled in Table 2 for ready comparison. The table also includes the results of the supplementary test series and gives the number of specimens tested of each variant.

It may be noted that a single median line has been drawn for all double-welded slip-on flanges, and the same has been done for the socket welding flanges. While these group averages are helpful in an over-all appraisal of the effect of the major design characteristics, a more detailed study of each individual variant in relation to others will be found worth while, inasmuch as it gives an idea of the contribution of minor details to the endurance strength of an assembly; while the differences between variants to be commented upon appear of a low order and well within the range of scatter of the test results, some of them are entirely too consistent and logical to be ignored, as will be shown. All comparisons will be made on the basis of the stress intensification factors developed, but it should be remembered that relatively small differences in this factor connote appreciable differences in fatigue life, i.e., the anticipated number of cycles to failure. As an example, a 10 per cent increase in stress-intensification factor is equivalent to a reduction in useful life under cyclic bending of over 40 per cent.

Single Welds. As expected, the butt weld used for attaching a welding-neck flange, test series C, was found vastly superior to any other form of attachment; it is equivalent to any butt weld between pipe, and practically as good as straight unwelded pipe. Even in an unfavorable location at the junction between two parts of greatly differing stiffness, as in socket welding variant B4, this form of weld gave a 13 per cent improvement over a similarly located fillet weld, as used in slip-on variant A4. As far as the two types of hub welds are concerned, i.e., the regular fillet weld and a weld deposited against a 52 1/2-deg reverse bevel or recess, neither the comparable single-welded variants (B31 versus B33,

and B32 versus B34), nor the double-welded ones (A2 versus A1 and B2 versus B11) show any consistent differences. Apparently, where both welds are of adequate size, the pipe failure is influenced solely by the contour at the toe of the weld, which is the same for both types.

Bottoming of Pipe in Socket. Having just mentioned variants B31, B32, B33, and B34, it may be opportune to cover briefly the second objective of this particular subproject, which was to discover whether butting the pipe solidly against the face of the recess in a socket-welding flange improved resistance to cyclic bending. From a comparison of the values of i , given for the condition with no gap with those for that with a 1/8-in. gap, it would appear that forcible contact of the end of the pipe with the socket face is helpful, but that the benefit is minor. Incidentally, the result of the slip-on flange series A3 would tend to confirm the results obtained on socket welding flanges with a definite gap.

Single Versus Double Welds. Three directly comparable groups of test series are available to evaluate the beneficial effect of the weld at the end of the pipe when used in conjunction with a hub fillet weld: Series A2 can be compared with series A3; series B31 and B32 with B2; and series B33 and B34 with B11. From such a study it may be concluded that the added welds produce an improvement in endurance strength of the order of 8 or 10 per cent.

Weld Proximity. There are indications that the distance between welds in double-welded flange attachments is not without significance: Below are listed the seven different variants of double-welded constructions tested, together with their stress-intensification factors; the order is from the closest spaced welds to those most widely separated:

B13:	1.11	} close (avg. 1.11)
B11:	1.09	
B2:	1.12	
D:	1.19	} intermediate
B12:	1.25	
A1:	1.19	} apart (avg. 1.24)
A2:	1.29	

Considering the two bracketed groups listed, it will be noted that a weld spacing not exceeding the height of the hub of a slip-on or socket welding flange on the average produces a 12 per cent higher endurance strength than a wider spacing, of the order of the flange thickness. Omitting test series B12 from the foregoing comparison, it will be seen that the two groups are directly representative of socket welding and slip-on flanges, and hence the former, when used with shallow sockets, can be pronounced about 12 per cent stronger against cyclic bending as compared with the latter.

The results for lap-joint and threaded-flange assemblies, as plotted in Fig. 9, and averaged in Fig. 1 and Table 2, require modification before they can be applied to piping design. It has been mentioned already that a slight loss in applied load was encountered in the case of lap-joint assemblies under high loadings; the plots are based on the initial loading (or strictly, the applied deflection), and adjustment to the approximate average loading over the test duration would raise the stress-intensification factor from 1.56 to 1.65, or reduce the life from about 11 per cent of that of straight pipe to only 8 per cent. In the case of threaded assemblies, seepage through the threads on the average occurred in one seventh of the time it took to produce structural failure. If we expand the definition of the "stress intensification factor" so that, for any given cyclic life, it expresses the relation between the stress producing fracture in a straight pipe and the stress producing failure from whatever cause in a comparative assembly (including the same kind of pipe), or in other words, if we consider leakage on equal terms with failure, this premature loss of serviceability of threaded flanges would have to be compensated by applying an "effective" stress intensification factor of 2.65 rather than 1.78 as obtained using cracking as the sole criterion of failure.

A few brief comments on the findings of the two supplementary test series included in Table 2 appear in order before going on to the conclusions. The one series, in which weld size effects were explored, indicated that it might be advisable for design purposes to increase the stress intensification factors obtained from the main test series somewhat for flanges involving attachment by fillet welding. The second series, involving thin-wall pipe, may be considered as providing a certain measure of assurance that, within the more common range of pipe sizes, the effect of the pipe-wall thickness and size or series of the flange is not overly significant.

CONCLUSIONS

The tests established that, even under unusually severe bending stresses, flange assemblies do not fail in the flange proper, or by fracture of the bolts, or by leakage across the joint face. Structural failure occurs almost invariably in the pipe adjacent to the flange, and in rare instances, across an unusually weak attachment weld; leakage well in advance of failure is observed only in the case of threaded flanges.

While it is the pipe that fails, the type of flange is influential in determining the endurance strength of the assembly, largely by the way in which it affects the stress transfer at the joint. The smooth tapering transition, afforded by a welding-neck flange, provides an endurance strength of the assembly equivalent to that of a butt-welded joint between two pieces of pipe, which itself is not greatly different from that of unwelded straight pipe to judge from indications obtained from tests in such pipe conducted by the authors. A fillet weld presents less favorable conditions owing to the sharp change in cross-section and stress-flow direction. In the case of lap-joint flanges, the transition would not appear unfavorable, but the lap apparently lends inadequate support to the neck of the stub end. Finally, in the case of threaded flanges, the reduced pipewall thickness and notch effect, caused by the threading, constitute weaknesses

which become even more apparent under cyclic loading than under static conditions.

In order to provide a quantitative measure of the relative endurance strength of different common flange assemblies, Table 3 has been prepared by the authors, using all the evidence produced in these tests, including the supplementary series and giving weight to any tendencies which may have been present of premature loss of serviceability prior to ultimate fracture. It is

TABLE 3 PROPOSED STRESS INTENSIFICATION FACTORS AND COMPARATIVE FATIGUE LIVES FOR DESIGN

Type of assembly	Stress-intensification factor, i	Relative fatigue life, p , per cent
Welding-neck flanges	1.00	100
Socket welding flanges (double-welded, with inside butt weld approximately in line with back of flange)	1.15	50
Double-welded slip-on or forged ring flanges	1.25	33
Single hub welded slip-on or socket welding flanges	1.30	27
Lap-joint flanges (with standard lap-joint stub ends)	1.60	10
Threaded flanges	2.30	1.5

thought that the stress-intensification factors given may find direct use in flexibility calculations following the rules of the Code for Pressure Piping, and that the parallel information on relative fatigue life, as more descriptive, may be helpful in setting limitations on flange types, depending upon the service involved.

ACKNOWLEDGMENT

The authors desire to acknowledge the co-operation of the management of Tube Turns, Inc., whose generosity in placing the facilities and personnel of its Research Department at their disposal made possible the investigation herein reported. The assistance in preparing the test assemblies, by welding the flanges to the pipe, rendered by Mr. John H. Zink, is also gratefully acknowledged. Mr. Zink, president of The Heat and Power Corporation of Baltimore, Md., is a member of the Subgroup on Flange Limitations of Subcommittee No. 3 of ASA B16, for the benefit of which the present investigation was conducted. Mr. Zink must also be given credit for proposing the design of the internally welded socket-weld flange which was included in the tests reported herein.

Discussion

H. F. MOORE.⁶ Full-size fatigue tests of structural and machine parts are always preferable to tests of small polished specimens when such full-size tests are feasible. Hence this paper is very welcome as it describes such full-size tests for flange-pipe assemblies.

The fatigue-testing machines used are of the simplest type—the type which measures directly the deflection of the specimen and the number of cycles of stress to cause fracture. The stress pattern, the load, and the bending moment are then measured from the deflection, using the specimen itself as the dynamometer. The authors determined the stress range from the deflection of the specimen, stopping the machine at various stages of the test to determine the steady value to which the stress range "settled down."

The authors carried out their tests to a maximum of about 2,000,000 cycles of reversed flexure. As is the case with railroad rails and with many structural parts, repeated-stress tests to 2,000,000 cycles are sufficiently long to cover the customary period of use. The results, plotted on log-log stress-cycle ($S-N$) diagrams show no sign of "flattening out," and show a con-

⁶ Research Professor of Engineering Materials, Emeritus, University of Illinois, Urbana, Ill. Mem. ASME.

siderable, although not too serious, scatter of test results. It is probable that longer tests would show a flattening out of the S-N diagrams. In that case extrapolation of the authors' results to 10,000,000, or even to 100,000,000 cycles might be expected to give results "on the safe side."

The writer is especially impressed by the poor showing made by the threaded flanges. Screw threads in any structural or machine part constitute one of the most dangerous of stress raisers, especially if the rod or pipe is screwed in as far as the thread will allow.

Attention is also called to the tabulation in Fig. 1 and Table 2 of both i , the effective stress-intensification factor, and to p , the ratio of length of endurance (number of cycles of stress) of a flanged assembly to that of the straight pipe. Thus the assembly can be judged on the basis either of comparison of stress range for a given endurance or of comparison of endurance for a given stress range of a straight-pipe specimen.

J. J. MURPHY.⁷ The authors are to be congratulated on having made a valuable contribution of test data on the performance of various flange types, on the organization of the tests, and presentation of the results for handy reference. There has been too little information available on this subject, and the paper is a fitting supplement to the senior author's previous paper.³

The role of fatigue-test data as an index to the relative serviceability of flange types is difficult to assess, and the authors have been careful not to draw any unwarranted conclusions. Data such as these are, nevertheless, quite valuable, and the order of performance of the various types fits in well with what would be expected, with the exception that the relatively poor performance of lap-joint flanges is somewhat surprising. While service experience with all types of flanges has been generally good, slip-on, lap, and threaded flanges are used normally only in the less severe services.

The tests provide excellent comparative data for the various weld details for slip-on and socket welding flanges. The ASME Boiler Code Subcommittee on Bolted Flanged Connections already has recognized a socket welding detail similar to B11 except that the inner weld is located at the mid-point of the flange thickness. The data here presented provide valuable information for permitting the weld to be located near the hub. The authors' opinion that the pipe failure is influenced solely by the contour at the toe of the weld appears logical, and it would be interesting to see if the performance of flange attachment B13 could be made to more closely approach butt-welded flange construction by modifying the fillet-weld contour as indicated in Fig. 10 of this discussion.

Also, it would be interesting to have comparative test data on threaded flanges with a seal weld, a construction which is widely used. The test data obtained in the supplementary tests provide valuable information on the possible effect of variations in weld quality and size to be expected in actual applications. It is

⁷ The M. W. Kellogg Company, Jersey City, N. J.

FIG. 10

noted that the performance of welding-neck flanges in the supplementary tests in Table 2 of the paper is the same as the main tests on flanges B11. The authors may wish to comment on this.

The bending moments applied in these tests simulate those which might be caused by mechanical vibrations or changes in temperature of the pipe line. Fluctuating pressures or cyclic temperature changes which cause the pipe locally to run cooler or hotter than the flange would impose a different-type loading on the attachment welds in that the shear and moment would be uniform around the circumference. It is possible that the performance of the various details would react somewhat differently to this type loading.

E. C. PETRIE.⁸ In interpreting the results of the authors' research investigations, the designer must consider the piping system as one integrated structure. In other words, it would be inconsistent to demand of a flanged assembly, resistance to fatigue of a much higher order than that required for another part of the piping system. Due precaution should be exercised, therefore, in attempting to draw all-inclusive conclusions from the results of a series of tests on only one size and class of product.

In order to illustrate this point, let us compare the test results obtained in the earlier Markl paper³ with those published in the present paper. The writer has combined these results in graph form in Fig. 11 of this discussion.

FIG. 11

It will be noted from this graph that the number of cycles to cause complete failure of the conventional and acceptable types of flange assemblies fall between those given for straight pipe and welding elbows. One exception is the welding-neck flange, which is slightly higher than that of straight pipe.

While it is a well-known fact that fatigue failures occur under certain conditions of severe stress in some threaded assemblies, there has been no indication, to the writer's knowledge, of failure in the side of a welding elbow due to fatigue as illustrated by the tests in the previous paper. The type of end fixation, notch effect in threads, clearances in flange assemblies, total resisting moment developed by bolting, are all important factors in an investigation of this type, and tests under various combinations may produce results which differ considerably from those presented in this paper. It is suggested, therefore, that more extensive investigations be made before arriving at any definite comparative values of fatigue life of elements which are component parts of a piping structure.

Another point mentioned in the paper being discussed is that the results obtained for lap-joint flanges indicate that "caution

⁸ Engineering and Research Division, Crane Company, Chicago, Ill. Mem. ASME.

is in order when using lap-joint flanges with laps of a thickness of the same order as the pipe wall in locations of high bending moments, since the lap apparently rocks back and forth on the gasket and tends to destroy it," but that "this was not the case for the lap-joint assemblies subject to low moments." Apparently the high moments referred to by the authors are not encountered in a properly designed piping system due to the fact that, to the writer's knowledge, this damage to the gasket has never been found under actual service conditions.

E. O. WATERS.⁹ Static stresses in piping and piping connections always have been given due respect. Somewhere along the road of acquiring knowledge of piping design, the effect of live loads caused by temperature differentials, and those due to rigid end connections and intermediate supports, were taken into account as a matter of course. However, even here the results of tests and theoretical analysis are mainly applicable to the pipe alone, and much still remains to be learned about the effect of live loads on flanged or other forms of piping connections, and on the vessels to which piping is attached. Most recently, the question of the endurance of piping systems subjected to dynamic loading has come to the fore, the chief reason for its importance doubtless being due to the substitution of welding for what might be termed "semipermeable" forms of pipe connection which always could be counted upon to leak profusely long before any structural failure took place.

The authors have made a factual statement of their findings without attempting any extensive analysis, and the question arises as to how best to interpret the results. In so far as the welding-neck type of joint is concerned, behavior was exactly as would be predicted; in this case, there are no sudden transitions in size of cross section, and no sharp re-entrant corners, the weld is inherently superior, and the flow of stress from flange to pipe follows comparatively straight lines and easy curves. At the other end of the scale, the poor showing of the single inside welds (series A4 and B4) was to be anticipated. However, there are several intermediate cases which give rather unexpected results, calling for further explanation. For example, the general setup in Fig. 1 of the paper would lead a superficial reader to conclude that socket-welded connections are, as a class, superior to slip-on connections. However, a closer inspection of the sketches in line 2 in Fig. 1 reveals that the quality of these connections is very sensitive to inside and outside weld proximity. In fact, the authors call attention to this point. This at once raises the question: If close proximity improves the performance of socket welds, would it not be possible to improve the slip-on group by inserting the pipe only part way into the flange? Also, from a comparison of series B11, B12, and B13, it appears that there is an optimum proximity beyond which a closer weld spacing impairs the fatigue life of the connection. This would seem to make further detailed study desirable, including if possible an investigation of the actual stresses at points of concentration, before truly quantitative conclusions can be drawn.

In conclusion, the writer would call attention to one feature wherein the tests showed remarkable consistency, namely, the location of the point or region of failure. This is consistent with static tests and theoretical stress analyses based on static loading, which always indicate a relatively high bending stress in the pipe that is intensified by a sudden transition from a comparatively thick flange to a thin-walled pipe. The inclusion of this stress as one of the criteria for the design of flanges has at times been a bone of contention among users of the ASME Unfired Pressure Vessel Code, on the ground that it imposed an unnecessarily severe restriction. However, the results of these fatigue

tests, as here reported, indicate that the existence of this stress, even though it is highly localized, cannot safely be ignored, at any rate when dynamic loads must be provided for.

AUTHORS' CLOSURE

The authors are appreciative of the lively interest exhibited in the tests reported by them, and value particularly those comments which raise the issue how the test data relate to service experience and what their significance is with respect to future piping design.

As has been pointed out in the discussion, there has been no published record of stress failures in service of the types shown in this and the senior author's earlier paper³, although failures in screwed joints, at branch connections and other points involving major stress raisers have been recognized as due to fatigue. One explanation, as inferred by Mr. Petrie, is that high sustained bending stresses, say, of 24,000 psi or over, are not encountered in properly designed piping systems; a second factor is that major stress cycles much in excess of 1000 over the life of a system are confined to the process industries, are not too frequent even there, and usually receive special consideration. Close inspection of Figs. 7, 8, and 9 reveals no stress failures of commonly used flanges within the quadrant defined by these limits, except in the case of threaded flanges, with lap-joint flanges coming close.

Accordingly it would seem that the tests and experience are in good accord. But, while experience proves that all but the two last-mentioned types of flanges will survive the conditions to which an average piping system is subjected, the tests are able to distinguish between the merits of the different types and thus offer an indication of how many more reversals at a given stress, or how much more stress at a given number of cycles, a welding-neck flange, for instance, can support with reference to any other variant. This is important in view of the trend toward more severe services in the process industries and the accompanying desire to liberalize allowable stresses; this latter objective can be accomplished, without reducing the true safety factor, only if our understanding of stresses improves so as to take part of the "ignorance component" out of the safety factor.

It is recognized that tests on a single size, class, and material of flange, with a specific type of gasket and bolting under a specific pull-up cannot be expected to form the basis for broad conclusions embracing the entire field of flanged connections. The authors, as some of the discussers noted, were careful to avoid such an impression. On the other hand, they feel that, considering the confirmation obtained from the supplementary test series, the results are suitable for engineering application to a somewhat broader range of conditions; in a way, there would seem to be no other alternative pending further experimental or analytical progress in this field.

A note of caution is in order with respect to comparisons of the type drawn by E. C. Petrie in Fig. 11. While the results of the flange tests might be applied with reasonable accuracy to a fairly wide range of sizes and thicknesses, those obtained for welding elbows are restricted to one specific size and thickness and can be extrapolated to other conditions only through the medium of a theoretical analysis, such as Beskin's development.¹⁰ Furthermore, moments due to expansion vary from zero to a maximum over the length of a line, so that a piping component with a lower stress-intensification factor situated at a location of high moment will often control even though other parts with higher factors are present in the line. The critical condition can only be properly evaluated by multiplying the stress at each significant location by the applicable stress-intensification factor.

¹⁰ "Bending of Curved Thin Tubes," by Leon Beskin, *Journal of Applied Mechanics*, Trans. ASME, vol. 67, 1945, p. A-1.

Many additional investigations have been proposed, and the authors would have wished to have been able to conduct these, but due to press of other work must confine themselves to giving answers which are no more than opinions.

J. J. Murphy's design, Fig. 10, might be expected to approach the welding-neck flange in performance, or at least equal the ring flange which behaved surprisingly well. A threaded flange with seal weld would probably be the equivalent of a single-hub-welded slip-on flange with minimum welding.

Professor Water's question, whether slip-on flanges would benefit from yield proximity to an equal extent as socket welding flanges is difficult to answer; the authors feel confident that they

would benefit, but perhaps not quite to the same extent as the socket welding type which can be reasoned to provide a somewhat better stress flow. No doubt there is an optimum distance between the front and back welds, but it is doubtful whether this can be determined from tests on commercially fabricated joints; a photoelastic analysis of models probably would furnish an answer.

Regarding J. J. Murphy's comment on the similarity in fatigue life of group B-11 and the supplementary welding-neck flange assemblies, no explanation can be offered except to point out that the results show a fair amount of scatter and hence overlapping between flange types of similar endurance strength.

Modern Mercury-Unit Power-Plant Design

By H. N. HACKETT¹ AND DWIGHT DOUGLASS²

This paper outlines briefly the general theory of mercury-binary cycle efficiency, how it works, and the more usual types of applications where it may be used. The use of the mercury-steam cycle as applied to topping plants is explained more completely with the relative capabilities of 140 psig mercury and 2300 psig steam for such service specifically compared. As a typical, as well as the most recent application of a mercury topping unit, the new 15,000-kw mercury-unit power-plant equipment recently installed at the South Meadow Station of the Hartford Electric Light Company is dealt with in considerable detail. In the manufacture of the mercury-boiler parts, factory prefabrication of relatively large mercury-furnace wall sections was successfully done for the first time. The new 15,000-kw mercury plant has been in operation since February 1, 1949, and for the month of February produced 20,000,000 kwhr of electric power at an average fuel rate of 10,200 Btu per net kwhr.

CYCLE EFFICIENCY

THE efficiency of a vapor cycle is determined largely by the saturated-temperature range through which it operates—the greater the range, the higher the efficiency of the cycle. This may be expressed by the equation, efficiency

$$E = \frac{T_1 - T_2}{T_1}$$

when T_1 and T_2 represent the saturated-temperature range through which the cycle operates, in degrees absolute.

The mercury cycle, superimposed on a steam cycle, boosts the efficiency of the resulting cycle because of the high boiling temperature of the mercury. For example, at 140 psig, mercury boils at 975 F, whereas at 1250 psig, water boils at 575 F.

With 975 F mercury and a proper selection of steam and fuel conditions, thermal efficiencies of from 34 to 38 per cent can be attained.

HOW THE MERCURY-STEAM POWER CYCLE WORKS

Fig. 1 shows a typical flow diagram of the mercury-steam cycle.

Heat from the burning fuel is absorbed by liquid mercury within the tubes of the mercury boiler to form mercury vapor, which passes from the boiler to the mercury turbine where it releases a portion of its energy to produce electric power. The vapor from the turbine is exhausted to the vacuum shell of the mercury-condenser boiler. There it condenses and releases its heat of vaporization to water within the tubes. The liquid mercury is returned from the sump, or hot well, to the boiler by a mercury feed pump, or by gravity, as the case may be.

The feedwater which absorbs heat from the condensing mercury vapor is boiled into steam at any desired pressure. This steam is then superheated in tubes located in gas passages of the

mercury boiler. This superheated steam is then available for driving a steam turbine, or may be put to other desired uses.

It is of interest to note that the steam thus produced by the binary cycle is only slightly less in amount than it would be if the equivalent fuel were burned directly in a steam boiler.

TYPES OF APPLICATION

A heat cycle or a power cycle upon which a higher-temperature heat cycle has been thermodynamically superposed may be said to have been topped. Hence a power plant composed of the higher-temperature cycle equipment may be known as a "topping plant." In reality, all power plants where binary cycles or superposed steam cycles are used, fall into the general class of topping applications. However, for the sake of simplicity, as well as for the purpose of easy identification, the types of applications for mercury-unit power plants have been divided into three general classes, i.e., topping plants, process or heating steam plants, and condensing plants.

A topping plant is one in which relatively high-pressure steam is desired, usually to be used in existing steam turbines.

A "process," or "heating steam plant" is one in which relatively low-pressure steam is required. If the steam is desired at a pressure below the minimum limit set for operation of the mercury-condenser boilers, it is then desirable to include a noncondensing steam turbine having its exhaust shell designed to exhaust the steam at a pressure suitable for the proposed application.

A "condensing plant" is one in which electric power only is produced. In this case, a condensing steam turbine of suitable size and design is included as a part of the mercury power plant.

The initial steam pressure and temperature for each of the three types of applications may be varied as dictated by existing steam conditions, or by the power-plant designer as he finds necessary in his effort to produce the most useful and economical over-all power plant.

RATIO OF MERCURY TOPPING KILOWATTS TO STEAM OUTPUT

A by-product kilowatt produced from a high-temperature topping cycle is obtained at nearly the mechanical equivalent of the thermal energy.³

Because of boiler and other machine efficiencies, by-product kilowatt output, as such, requires the expenditure of approximately 4000 Btu per hr from the fuel, regardless of whether the topping kilowatt-hour is produced by a steam topping turbine or a mercury topping unit.

Another way of indicating this situation might be to say, that whenever a heat power plant or a portion of a heat power plant is credited with heat rejected, then the net heat consumption of the kilowatts generated in that portion of the power plant is equal to heat put in minus heat rejected to the next portion or system, divided by the kilowatts produced; and that this is usually in the neighborhood of 4000 Btu per kwhr.

Mercury topping plants as generally applied, will produce about twice as many 4000-Btu kw per 1000 lb of high-pressure steam as can be secured from other topping cycles. Furthermore, a mercury topping plant, designed originally to produce, say, 400-psig steam, may be used if desired to top 850-psig steam, or higher, merely by altering the size of the steam superheater and changing the steam safety valves, if allowance has been made in the design

FIG. 1 TYPICAL FLOW DIAGRAM OF MERCURY-STEAM CYCLE

for the stresses which will be encountered at the desired pressure.

Fig. 2 gives a clue as to why mercury-topping power ratios are so high. In this comparison, the total heat of the mercury vapor and its competitor, high-pressure steam, have been corrected to the same total heat as is contained in 1 lb of 2300-psia 1050-F total temperature steam, or to 1497 Btu. For this total heat, 9.7 lb of mercury vapor must flow through a mercury turbine for each pound of 2300-psia steam flowing through a 2300-psi steam turbine.

As a basis for comparing the topping capabilities of these two cycles, the upper curve is a plot of the available energy of approximately 9.7 lb of mercury vapor when used to produce topping steam at various pressures in the mercury-condenser boilers. The lower curve is a plot of the available energy of 1 lb of 2300-psia steam used in a turbine, exhausting at the indicated back pressures. The steam pressures thus indicated by the abscissa are the back pressures of the steam expansion from the 2300-psi noncondensing steam turbine, or the pressure of the steam made in the mercury-condenser boilers. In keeping with present design practices, a 30-deg F terminal difference between the condensing mercury vapor from the mercury-turbine exhaust, and the boiling water was taken into account when establishing the mercury-vapor available-energy figures.

It will be noted on the chart that at 400-psia steam pressure, the available-energy ratio of mercury to steam is 442/220, or almost exactly 2 to 1, and, at 1250 psia, the ratio is 320/87 or almost 3.7 to 1.

The fact that the available energy of mercury vapor varies only some 27.5 per cent when generating steam in the mercury-condenser boilers at pressures varying from 400 psig to 1250 psig, makes it possible to design standard mercury units for wide ranges of by-product-steam pressures with a relatively small change in mercury-turbine output.

Over the same back-pressure range, the available energy of a 2300-psig noncondensing topping turbine varies about 60 per cent.

Further, the mercury power plant may be used effectively operating in conjunction with 850-psig or even 1250-psig steam turbines to increase greatly the over-all plant capacity and efficiency.

A steam-turbine plant capacity may be increased some 60 per cent for the same quantity of condensing water by mercury topping. For example, the new Schiller Station at Portsmouth includes a 25,000-kw steam turbine which, in effect, is topped with 15,000 kw of mercury capacity. For the 40,000 kw total capacity, only 25,000 kw are affected by the usual condenser losses. This saving in condenser-cooling-water requirements may become very important in localities where cooling water is scarce, although this was not the case at Portsmouth.

MERCURY TOPPING AT SOUTH MEADOW

The South Meadow Station of the Hartford Electric Light Company was the first steam-generating plant to use a mercury-vapor cycle to top existing steam-generating units as a commercial undertaking. This original 10,000-kw mercury topping plant was

FIG. 2 AVAILABLE-ENERGY CURVES FOR MERCURY VAPOR AND STEAM

(The available energy of 155 psia 975 F total temperature mercury vapor and 2300 psia 1050 F total temperature steam have been corrected to the same total initial heat of 1497.1 Btu. The curves are then plotted with actual available energy of the two corrected fluids as the ordinate with the abscissa representing the back pressure of steam expansion of a 2300-psia noncondensing steam turbine, or the steam pressure generated in the mercury-condenser boilers. The mercury-turbine exhaust pressure has been corrected to include a designed drop of 30 deg F terminal difference in the mercury-condenser boilers.)

put into service in 1928, superposed on 250-psig 700 F total temperature steam-generating equipment installed in 1921. The design margin in the steam portion of this first mercury installation was ample to permit the raising of its operating pressure to 400 psig 700 F total temperature early in the 1930's simply by changing the safety valves.

In the 19 years between 1928 and 1947 this first commercial mercury topping plant operated on line for some 119,000 hr, producing a net output of more than 1.7 billion kwhr of electric power.

It was evident prior to 1946 that the original installation, constructed from materials available in 1927, was coming to the end of its economical life owing to the metal fatigue at the associated high operating temperatures. The Hartford Electric Light Company made an economic study of the value of a 50 per cent larger-capacity unit in the same building with the result that it was decided later in 1946, to proceed with active engineering of a modern replacement for the 1928 unit and its associated equipment.

The removal of the old equipment was started in the summer of 1947, to make the building area available for the installation of an entirely new design of mercury plant having a capacity at full load of 15,000 kw, and a steam output from the condenser boilers of 210,000 lb per hr at 400 psig 700 F total temperature.

NEW 15,000-KW MERCURY-UNIT POWER-PLANT EQUIPMENT

The mercury-unit power-plant equipment now in operation is entirely new except for the condenser-boiler steam drums and vacuum shells, the mercury-turbine generator, and a portion of the mercury-turbine exhaust shell. In order to assure reliable operation of the condenser boilers, new steam-generating tubes with water circulators were installed. Because of the ample size of the 10,000-kw generator stator frame and rotor, these parts were rewound to give maximum output of 15,000 kw at unity power factor.

Most of the existing building steel, as well as certain of the old boiler supporting members, were usable with the new equipment. However, as might be expected, the major portion of the equipment structural supports had to be replaced to meet the new design conditions.

Fig. 3 shows a schematic arrangement of the main equipment as it is now installed in the South Meadow Station.

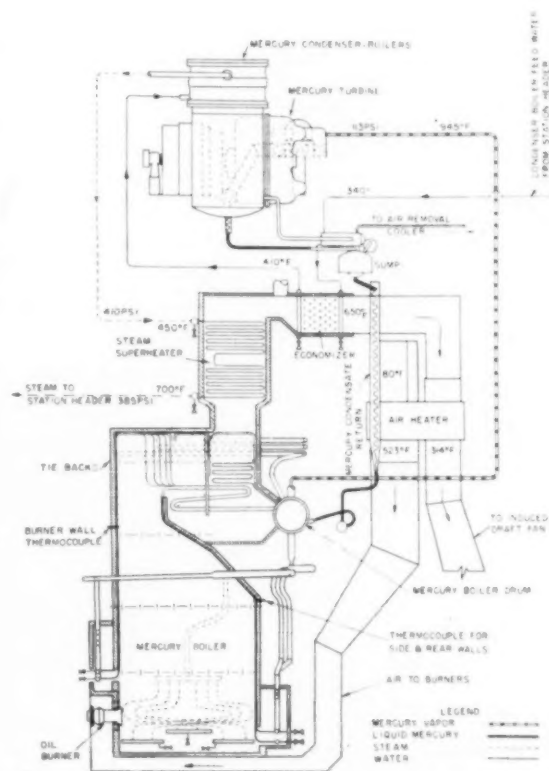

FIG. 3 SCHEMATIC ARRANGEMENT OF 15,000-KW MERCURY-UNIT POWER PLANT AT SOUTH MEADOW STATION

The oil-fired mercury boiler is of the latest design, having completely mercury-cooled furnace, slag screen, and mercury fog-convection surfaces. The steam superheater, water economizer,

and regenerative-type air preheater are of conventional design, as are the forced and induced-draft fans.

Mercury vapor is generated within the tubes of the mercury boiler at a pressure of 130 psig and at a saturated temperature of 964 F. The mercury vapor thus produced flows upward through four 12-in. vapor pipes to the five-stage single-flow mercury turbine located in the turbine room above the mercury boiler. Suitable mercury stop and throttle valves are attached directly to the mercury-turbine high-pressure shell for controlling the mercury-vapor flow to the turbine. Likewise, two 14-in. mercury-boiler relief valves are mounted out from the inlet end of the turbine stop valve to protect the mercury boiler from overpressure. When operating, these two relief valves discharge into the condenser-boiler vacuum shell where the energy from the overpressure mercury vapor is absorbed to produce steam which may then be used by the steam-turbine units, or exhausted to atmosphere through the condenser-boiler steam safety valves, depending upon the station load conditions.

The mercury turbine exhausts into two vertical-type side-mounted mercury-condenser boilers at an exhaust pressure of 1.5 psia 480 F. In condensing, the exhaust mercury vapor releases its heat of vaporization to water within the tubes of the condenser boilers to produce steam at 410 psig. The condensed mercury liquid then flows by gravity through a cleaning sump and suitable piping system to the mercury boiler where it is again evaporated at 130 psig.

The steam generated in the condenser-boiler tubes is superheated by the boiler flue gases to 700 F total temperature in the steam superheater mounted directly above the mercury boiler. The steam thus superheated is piped to the 385-psig station steam header for use in the 385-psig steam turbines.

When desired, steam may be generated for use with the 250-psig steam turbines. No equipment alterations are necessary as the change-over may be made from one station steam pressure to the other merely by valving the steam superheater-outlet pipe to the desired steam header.

The condenser-boiler feedwater is taken from the station feedwater header at 340 F, pumped through the cooling coils of the primary air-removal cooler and into the water economizer, where it is heated by the boiler flue gases to 410 F. The heated feedwater then flows into the condenser-boiler steam drums where it is boiled into steam by the condensing mercury vapor.

In order to assure satisfactory over-all power-plant combustion efficiency, a large regenerative-type air preheater heats the air used for combustion from 80 F to 523 F. The resulting exit-gas temperature with 15 per cent excess air leaving the furnace is expected to be 300 F, when corrected for air leakage through the air preheater.

MERCURY BOILER

A mercury-furnace tube operated with properly treated mercury is capable of pumping large quantities of liquid mercury and vapor through long flow circuits located considerably above the liquid level in the boiler drum. This action is produced by the relatively high pumping head of the down-flowing liquid column supplying the lower feed headers of the furnace tubes, as well as from the proportionately high available energy in the expanding mercury vapor as it flows upward through the boiler tube. The release of energy is brought about by the large change in pressure throughout the tube from where boiling first occurs in the lower portion of the furnace to where the tube enters the boiler drum at operating pressure. In a very high boiler this pressure head may be 100 psi or more.

As heat is applied to the boiler tube, generating more and more vapor, the theoretical density of the flowing mixture may change from solid liquid, weighing approximately 778 lb per cu ft, to a lean

mixture having a weight of approximately 2.5 lb per cu ft, before decrease in heat-absorbing ability of the tube occurs. In actual mercury-boiler designs, such as the 15,000-kw Hartford boiler, the mixture discharging into the boiler drum from the fog-convection tubes is designed to be in the order of 13 lb per cu ft for the heaviest loaded circuit. Such a mixture contains approximately 1 lb of vapor for each 7 lb of liquid mercury circulated, or may be said to have a circulation ratio of 7:1.

The economic advantage of such circuit design is immediately apparent as great savings in total boiler mercury are possible, since it is only necessary to fill the furnace tubes with mercury to a minimum depth with no liquid mercury in the fog-convection portions of the circuits at starting. The liquid portions of the tubes can be of small internal diameter while the fog section tubes may be much larger.

A mercury boiler usually requires some 70 to 80 per cent of the total heat-absorbing surface in the convection regions, and if it were necessary to use all liquid-filled tubes, the quantities of mercury required might be prohibitive. This theory of mercury-boiler design was first used successfully in 1940 in the 20,000-kw mercury boiler at Kearny where many of the fog circuits are some 250 ft long from end to end with approximately 40 ft of the furnace portion of the tubes liquid-filled at starting.^{3,4}

These simplifications and economies are possible because the titanium-magnesium-treated mercury in the boiler circuits produces intimate and perfect contact between the metal of the tubes and the flowing mercury. The treated mercury has lost its spheroidal properties and spreads in a tenacious film over the inside walls of the tubes, forming a "wetted" surface from which evaporation of the mercury occurs.⁵

The tenacity of the wetted film is such that it is not destroyed when superheated upward to 200 F above the temperature of the saturated-vapor-liquid mixture flowing in the circuit, as long as treated mercury is supplied to the heated film as rapidly as evaporation occurs. By maintaining suitable velocities of the flowing mixture in the tubes, the required "make-up" supply of mercury droplets is available over the extremely wide range from solid mercury liquid to the approximately low density of a 1.2 parts by weight of liquid mercury to 1 part-vapor.

The extensive use of mercury-fog-convection surface throughout the entire boiler reduces the maximum pressure at any point in the tube circuit, which subsequently reduces the boiling temperature of the mercury and the metal temperature of the tube steel. This allows added protection against oxidation of the tube metal on the fire side of the tubes, as well as increases the allowable working stress of the material.

Our standard-design, mercury-unit-power-plant mercury boilers, of which the 15,000-kw Hartford unit and the three 7500-kw units for Pittsfield and for the Schiller Station are typical examples, all utilize the well-proved principle of fog-circuit design.

THE HARTFORD MERCURY BOILER

Fig. 4 is a cross section of the Hartford boiler. The flow of mercury in the various boiler circuits is simple and direct. The operating liquid level is maintained at or near the inside bottom of the boiler drum. With the boiler in operation, the fluid mercury flows from the drum downward through suitable downcomer supply pipes to the various lower headers, and then upward to the drum, as required, to provide coolant for the furnace tubes and fog-convection circuits.

Owing to the simplicity of the mercury-boiler design, only four basic types of tube-flow circuits were required.

The tubes covering the two furnace side walls are simple

³ "The Mercury-Vapor Process," by A. R. Smith and E. S. Thompson, October, 1942.

FIG. 4 CROSS SECTION OF 15,000-KW MERCURY BOILER
(Portion of furnace tubes, downflow slag screen, fog-convection tubes, drum and downcomer supply system, as well as steam superheater and water economizer are shown.)

straight-through elements receiving mercury from bottom headers and discharging into vapor headers at the top. Each of the six vapor headers connects to the mercury-boiler drum through a vapor discharge pipe. The side-wall furnace tubes are $1\frac{1}{2}$ in. OD \times $\frac{7}{8}$ in. ID for the lower 16 ft and are 1 in. ID for the remaining 30 ft of their length.

The burner-wall or front-wall tubes supply mercury to the roof section of the furnace vestibule, the vertical downflow slag-screen tubes, the first and second passes of the horizontal fog-convection tubes, and finally discharge into the drum. These tube circuits are stepped in size from $\frac{7}{8}$ in. ID, where they leave the lower headers, to $2\frac{1}{2}$ in. OD \times $1\frac{3}{4}$ in. ID, where they form the first-pass fog bank.

The rear-wall furnace tubes also form the sloping roof section under the fog-bank assemblies. A number of the roof tubes are directed upward and function as the two mercury-cooled supports for the fog circuits. These tubes then continue on to form the

FIG. 5 15,000-KW MERCURY FURNACE SIDE-WALL ASSEMBLY BEING HOISTED INTO POSITION
(Showing sections already in place, a third section being hoisted into position to complete east furnace wall.)

third-pass fog circuits. The remainder of the roof tubes protect the nose of the furnace arch and then turn back and become a portion of the first and second-pass fog banks. The tube sizes vary from $1\frac{1}{2}$ in. OD \times $\frac{7}{8}$ in. ID at the bottom to $2\frac{1}{2}$ in. \times $1\frac{3}{4}$ in. where they form the fog circuits.

In an effort to reduce over-all costs as well as to reduce the time required to complete field assembly of the boiler units, factory fabrication of the furnace tubes with their liquid and vapor headers was tried for the first time. Fig. 5 shows one of the furnace-side-wall subassemblies of which there is a total of six, three for each side wall. These are approximately 7 ft wide \times 46 ft long. Some 47 tubes are completely assembled with their upper and lower headers, tiebacks, and supports ready for placing in position in the boiler-supporting steel. Similar but small subassemblies of the front and rear-wall tubes likewise were made at the factory and shipped ready for field erection. The fog tubes, slag-screen tubes, and the upper portions of the front and rear-wall tubes were handled as individual pieces in the field. However, the apparent savings in erection time and over-all cost seemed to be sufficient to warrant further development of factory prefabrication of mercury-boiler parts. Therefore similar but more complete subassemblies were manufactured for the three 7500-kw units now in the process of being erected.

Fig. 6 shows the upper portion of the completed Hartford furnace.

Fig. 7 shows the six horizontally mounted fuel-oil burners. These six burners are mounted under the front-wall tube headers near the bottom of the refractory furnace bottom.

MERCURY-BOILER DESIGN AND MANUFACTURE

The three 7500-kw boilers for Pittsfield and the Schiller Station are of identical design and are being manufactured by the Babcock & Wilcox Company from identical blueprints. The Hart-

(View shows upper portion of furnace walls, sloping arch and furnace roof. Downflow screen tubes are also shown above sloping roof sections.)

ford boiler, manufactured and installed by the Foster-Wheeler Corporation, differs somewhat from the 7500-kw boilers in that it was designed with a flat refractory-covered furnace floor for burning fuel oil only. The 7500-kw units have dry-ash mercury-cooled hopper-bottom furnaces for burning pulverized coal or fuel oil as desired.

FIG. 7 SIX HORIZONTALLY MOUNTED FUEL-OIL BURNERS
(Lower end of front-wall furnace tubes, refractory burner wall, and refractory furnace bottom are shown.)

MERCURY-TURBINE GENERATOR

Fig. 8 shows the 10,000-kw Hartford turbine after 16 years' operation. This simple single-flow 720-rpm, five-stage turbine has run more than 116,000 hr since its last internal inspection. When finally dismantled in 1947 for replacement, the machine internals were found to be in unbelievably good condition for a unit that had operated without internal maintenance for such a period of time.

However, because of the design conditions at 15,000-kw output, requiring the use of higher pressure and temperature, it was necessary to replace the old mercury turbine completely, using the latest in materials and machine design. The new machine followed the general pattern of the original unit but included all of the modern improvements, such as mercury-sealed shaft seals, and vanadium-molybdenum alloy castings for the high-pressure turbine head, turbine control, and stop valves, and for the mercury-boiler relief valves. A complete new turbine-rotor assembly, having separately mounted split diaphragms, was provided. A new main bearing, incorporating a double-thrust-type thrust bearing, was also necessary. Because the unit was to be operated as a base-load machine, no speed governor was installed. Two emergency trips were provided, one on the hand-operated control valve, and one on the turbine stop valve.

Fig. 9 is a view of the mercury turbine with the four split diaphragms in place and the high-pressure head removed. The two wing-back-mounted condenser boilers have been placed in position ready for making the two large turbine-exhaust-shell welds.

Fig. 10 is a view of the exhaust opening of the east condenser boiler, showing the porcupine-type tube bundle.

Fig. 11 shows the completed assembly of the mercury turbine, condenser boilers, control and stop valves, and the mercury-boiler relief valves.

HARTFORD ELECTRIC LIGHT COMPANY OPERATING EXPERIENCE

Previous Designs. The Hartford Electric Light Company operating experience with the mercury cycle for power generation covers the period beginning in 1923 up to the present date.

FIG. 8 10,000-KW MERCURY TURBINE BEING DISMANTLED IN 1947 AFTER 16 YEARS OF OPERATION IN SOUTH MEADOW STATION

FIG. 9 15,000-KW MERCURY TURBINE BEING ASSEMBLED IN 1948, SOUTH MEADOW STATION

(View shows portion of original 10,000-kw turbine-exhaust shell, original but newly retubed condenser boilers, and partial assembly of new wheels and new built-up diaphragms. Split interstage diaphragms were used in new machine rather than the old shell-supported solid-disk type shown in Fig. 8)

During the first 4 years it was a joint venture with the General Electric Company for the purpose of developing a design that would meet all the requirements of a central station from the

FIG. 10 MERCURY-CONDENSER BOILER SHOWING PORTION OF PORCUPINE-TYPE TUBE BUNDLE AND OPENING FOR ATTACHING TO MERCURY TURBINE-EXHAUST SHELL

(Downflow water circulators were installed in each steam-generating tube to improve circulation.)

point of flexibility, dependability, and economy. This first topping unit was installed in the Hartford Electric Light Company's Dutch Point plant and consisted of a 1500-kw generator, driven by a mercury-vapor turbine exhausting to a condenser-boiler operated at 200 psig and 540 F total temperature, the conditions of the main steam header in the plant. Five entirely different designs of boilers were covered in this experience cycle.

In 1927 a 10,000-kw mercury-vapor unit was contracted for as a plant extension at the South Meadow Plant to top an existing 250-psig, 700 F total temperature steam unit installed in 1921. This design was proved by the Dutch Point experience but in the larger size developed several faults. Consequently it was 1932 before all defects had been eliminated and the plant could be considered as dependable central-station equipment.

From 1932, until its removal in 1947, the 10,000-kw South Meadow unit operation was quite satisfactory even though it was necessary to reduce top operating load progressively as metal fatigue progressed. By thus reducing load, and consequently stresses, we were enabled to produce the results given in the first section of this paper at an over-all plant availability in excess of 85 per cent. This availability includes outage time for steam-cycle equipment as well as that for the mercury cycle.

Operation of 10,000-Kw Unit. Operation of this 10,000-kw unit was extremely simple: Liquid mercury was returned by gravity to the boiler; there was no treatment of the liquid-mercury charge; no treating of the boiler feedwater was required; there was no complicated feed-heating cycle, and the pressures were low.

Mercury replacement, due to all losses, was low, averaging less than 2000 lb per year from all causes both avoidable and unavoidable.

Maintenance was variable. General maintenance was usual for

Fig. 11 ASSEMBLY OF 15,000-KW MERCURY TURBINE, SOUTH MEADOW STATION

(High-pressure shell control and stop-valve assembly with 26-in. mercury-vapor inlet pipe entering bottom of stop-valve casing. One of two 14-in. mercury-boiler-relief valves with their 18-in. vapor-relief pipe is shown attached beyond vapor-inlet pipe. Boiler relief valves discharge their vapor, when operating, into west condenser boiler.)

all associated equipment and there was no maintenance on the mercury turbine from 1931 until it was dismantled in 1947. The mercury boiler required a major internal cleaning approximately once a year using acid, and external cleaning at the same intervals as a steam boiler. As a general statement, it should be said that average maintenance costs for this unit were slightly in excess of those for a comparable steam unit.

NEW 15,000-KW MERCURY PLANT AT SOUTH MEADOW

While construction work had not been completed it had progressed to such a point that it was possible to light the first fire under the boiler on January 2, 1949. Preliminary operation consisting of boiling out, trying out all associated apparatus, and making indicated changes and adjustments had been completed by January 8, and the mercury-vapor-driven generator was phased in on the line. By February 1 construction work had been completed, the changes indicated by the first two runs had been made, and the unit phased for service the third time. The plant had been accepted for service with this third start and the results of this operating period are shown in Table 1.

All quantities shown in Table 1 are actual net figures, as all charges have been made to the mercury plant occurring from associated auxiliary equipment whether it is a part of the mercury plant directly or a part of the steam-turbine unit using the steam from the condenser boilers.

Shutdown of the unit at the end of 28 days of operation at full load was caused by a partial stoppage in the regenerative air

heater. Thorough inspection, during this shutdown, indicated that all parts of the mercury cycle were in as good condition as at time of the start-up.

CONCLUSION

From the Hartford Electric Light Company's experience to date, no serious difficulty is anticipated with any part of the equipment covered by the new design. The plant forces are adequate to handle all phases of the new problems introduced by the necessary chemical treatment, the special metals used in fabrication, and the novel instrumentation.

The operating economies have been proved, and the design demonstrated as generally adequate.

ACKNOWLEDGMENT

In the Hartford boiler, and also the three 7500-kw units, the basic boiler design, the treatment of the boiler mercury, and the design and size of the boiler flow circuits is by General Electric Company. However, such problems as structural supports, fuel burning, and over-all boiler performance, as well as actual detail designs, manufacturing, and erection of the complete boiler units could best be done by the boiler manufacturers. Joint responsibility was shared by the General Electric Company and the boiler companies with regard to the materials used in the tubes and other pressure parts.

This broad division of responsibility has offered no problems whatsoever of customer relations between either the General Electric Company as principal contractor and the boiler companies or operating companies in carrying out the several projects now under way. The relationship has been most cordial and all parties concerned have spared no efforts in promoting vigorously their various portions of the work. We particularly wish to congratulate at this time those of the Foster-Wheeler Corporation who have worked with such diligence and painstaking care in making the Hartford boiler such an outstanding success.

Discussion

WILLIAM KOWALSKY.⁵ Another step toward widespread commercial acceptance of the mercury-vapor steam cycle for power generation has been taken with the successful completion of the mercury power unit at the South Meadow Station of the Hartford Electric Light Company. The heat-rate data given in Table 1 of this paper will be a criterion against which other utilities may check their own plant performances.

For the writer's company, the work of planning, fabricating, and erecting the mercury boiler was an unusual and valuable experience. Each stage of development of the mercury boiler was preceded by exhaustive tests and investigations. No material or procedure was adopted until tried and proved. (It should be emphasized that this approach was used by General Electric Company from the very beginning of its experiments with the mercury-vapor process back in 1912. This step-by-step development can be pointed out as a classic example of the solution of an engineering problem in which there was no previous experience and where every item involved unknown elements.)

From a metallurgical standpoint, there were commercial alloys available for the furnace tubing which could withstand the 1100 F metal temperature and the 1000 F mercury temperature, but fabricating methods, welding, heat-treating, and stress-relieving procedures had to be developed. The difference between shop- and field-welding procedures had to be investigated. With the operating-temperature range mentioned, creep strength limited the design stresses, and considerable stress-analysis work was done to insure that the low permissible stresses were not exceeded. The boiler was designed to meet the requirements of the ASME Boiler Code in so far as possible.

Due to high metal temperature, it was necessary to select materials with high resistance to oxidation. High-silicon steels were selected. It is estimated that these superior materials give the mercury boiler the same economic life as a modern steam generator. The tube material for all of the furnace, slag screen, first-pass convection tubes, and eighteen rows of second-pass convection tubes, corresponded to SA-213-T13. The upper bank of second-pass convection tubes had a composition very similar to SA-213-T21. The mercury drum, downcomer system, upper and lower headers, conformed to SA-213-T12. Thus expensive alloys were used only where needed, as dictated by boiler conditions. Tube supports, fixed ties, and tie-back supports, when exposed to furnace or boiler temperatures, were normally of 25-20 alloy composition. The SA-213-T13 tubing (4 to 6 chrome, $\frac{1}{2}$ moly, 1 to 2 silicon) was welded by the atomic-hydrogen method, using a bare rod of the same composition as the tubing. The SA-213-T21 (2.75 to 3.25 chrome, 1 moly alloy) tubing was welded by electric arc with a 2 chrome 1 moly coated rod. The SA-213-T12 tubing (chrome-stabilized carbon-moly) was welded by electric arc with a $\frac{1}{2}$ chrome $\frac{1}{2}$ moly coated rod. Backing rings for all welded joints were of the integral type, machined right on the tube to form the male end, with a standard bevel machined in the matching tube for the female end. All welds in which SA-213-T13 material was involved, were ground and magnafluxed. Only random welds of the other compositions were ground and magnafluxed. A proof of the welding quality of the total volume under pressure or vacuum can be seen in the extremely low air leakage into the system.

The superheater is of the continuous-tube type of carbon-steel material. Because the superheater occupies the tail position in the boiler, and because of the variable mercury-pressure operation, the superheat characteristic drops very sharply as the load decreases. To get the maximum performance of the steam end at fractional loads, a group of parallel dampers have been installed

to by-pass the upper second-pass convection surface, and thereby increase the heat available for steam superheating.

In order to save time and expense in the field, and in order to accomplish as much of the welding as possible under shop conditions, the mercury-cooled walls were assembled in fourteen sections in the shop. The elements were fabricated, welded into the headers, and then stress-relieved as complete units. This was the first time a boiler had been shipped in such large flexible prefabricated assemblies. Necessarily, this procedure involved solving numerous problems, such as handling methods, assembly jigs, railroad clearances, erection clearances in the building, and so on.

The mercury boiler is supported across the front and rear at the level of the bottom of the mercury drum and is allowed to expand up and down from that point. The side walls are supported at the top of the furnace. Vertical expansions are of the order of 3 in. and require provision for flexibility in connecting downcomer piping to the riser side, a problem which was complicated by the much colder mercury on the downcomer side. Tie-backs are spaced at approximately 10-ft intervals and arranged for each tube to move laterally and vertically, independently of its neighboring tube.

During the initial start-up of the mercury boiler, when all concerned were crossing fingers, praying to the "gods of kilowatts," and trying hard to look unconcerned (even though we knew that every care and precaution possible had been taken), it was a source of wonderment to the writer to find how correctly the General Electric Company designers had predicted the behavior of this mercury boiler. When circulation of mercury was still erratic and efforts to induce some kick-over of hot mercury into the drum and downcomer system to try to equalize temperatures and expansions were being made, the prediction was offered that, starting at 4000 kw output, there would be some audible thumping of slugs of mercury in the vapor tubing, and that this would quiet down at 6500 kw. It worked exactly as predicted. We knew that untreated mercury did not "wet" the inside tube surfaces and that this caused erratic heat-transfer rates. We also knew that mercury with small amounts of magnesium and titanium did wet the inside tube surfaces and allow a uniform heat flow into the mercury. Nevertheless, we had to rub our eyes when we actually saw this happen. When circulation was established, our thermocouple readings indicated wide variations in first-pass convection-tube temperatures. Within a few minutes after the treating chemicals had been injected into the mercury feed lines, the temperature of these tubes dropped approximately 100 deg F, and all reached a more-or-less uniform level. It was obvious that the heat-transfer rates had suddenly become dependable.

The early mercury-boiler designs were complicated, but now it is just like any steam generator in appearance, both from the outside and from the inside of the furnace. The low position of the mercury drum with relation to the top of the furnace tubes strikes one as unorthodox at first glance; moreover, there is no level of mercury in the drum, a condition in which steam boilers are shut down promptly. The unit is specially developed and designed to run on minimum mercury content, which is possible because of the ability of mercury vapor to entrain substantial amounts of mercury mist or fog of tremendous cooling effect. It is necessary of course to supply a liquid mercury fog to the upper tubes to keep the film of mercury, which coats the inside tube surfaces, supplied with chemically treated mercury to replace that which has been evaporated. Provided reasonable mixture velocities are maintained, there is no limitation in size or shape of the tube circuits. The length of the tube circuit could be considerable, depending on the available mercury-circulating head and heat input. As long as treated liquid mercury mist is carried by the vapor, there can be no overheating of the tubes.

⁵ Project Engineer, Foster-Wheeler Corporation, New York, N. Y.

The Hartford mercury boiler was not built as another experimental attempt to improve the Emmet mercury-vapor process. It is just another boiler built on a purely commercial basis of sound economics, because the practicability of the system has been proved before.

H. WEISBERG.* At the Kearny Station, Public Service of N. J., there is installed a 20,000-kw superposed mercury-turbine generator which has been in operation since 1933. The combined mercury-steam capacity is 45,000 kw. For the first 6 years this unit was in service 51 per cent of the time, and generated over 750,000,000 kwhr; the average output being 32,000 kw.

In 1940 the boiler was replaced with a more modern design, somewhat similar to the new Hartford boiler. In the 9 years since then, the unit has been in service 72 per cent of the time. It has generated over 2,100,000,000 kwhr, and has had an average output of 38,000 kw. The total generation for both installations has been about 3,000,000,000 kwhr.

At the present time the unit is in regular operation on the system at loads up to full rated capacity. Early next year rather extensive repairs are planned to the furnace tubes owing to wastage on the gas side. Also, the vapor piping and control valves, which are plain-carbon steel and operate at 970 F, will be replaced with alloy-steel parts. It is expected that as a result of this work, along with other improvements which have been made in recent years, the availability of the unit will approach that of steam units, which is better than 90 per cent.

The heat rate of the unit, combined with 1925 design, 355-psi, 725-F steam capacity, compares favorably with the most efficient steam units which we are installing today, and as a result, with the inflation that has taken place since 1933, the value of the unit on the system is about double the original cost.

We are often asked whether we would install another mercury unit, or why we are not installing mercury units now rather than steam. The answer is that the availability up to the present time has not been as good as that of steam. It is our belief that the troubles we have had are not inherent in the mercury cycle and have been overcome by operating experience and development. With the present state of development, however, it seems inadvisable to build mercury boilers in capacities of 125,000 to 150,000 kw, which size steam units can be utilized safely on a system as large as that of the Public Service. This results in considerable disadvantage in the first cost of mercury units when compared with steam.

The mercury cycle when combined with modern steam capacity is more efficient than any steam cycle currently practicable, and therefore it is attractive where fuel costs are high and a unit not over 45,000 kw combined capacity is needed. Larger units would require two boilers and would be less economical. For superposition in sizes not over 20,000 to 30,000 kw, the mercury cycle is even more advantageous. Here again, if any of the Public Service units were to be superposed now, considerably larger units could be considered, and the mercury cycle would be at a disadvantage compared to steam. For these reasons we have not been able to justify additional mercury capacity on recent installations.

Summing up, 16 years of experience with the mercury cycle indicated definite and continuing progress. Additional installations appear to be justified at this time in limited sizes and for special applications.

O. L. WOOD.† There are many interesting details of the new

* Mechanical Engineer, Electric Engineering Department, Public Service Electric and Gas Company, Newark, N. J. Mem. ASME.

† Construction Engineering Division, General Electric Co., Schenectady, N. Y. Jun. ASME.

mercury installation at Hartford which might be used to supplement the comprehensive paper presented by the authors. The writer, however, will discuss only some of the phases of installing the new equipment, which is of 50 per cent greater capacity and operating pressure, within the space occupied by the original unit.

The original operating boiler pressure of 85 psig 908 F saturation was increased on the new unit to 130 psig 964 F. This was done, as explained in the paper to obtain (1) greater cycle efficiency by having the total heat available at a higher initial temperature, and (2) more available energy per pound of vapor.

The increase in capacity, requested by The Hartford Electric Light Company, was based upon its studies of a replacement and the real economies obtained on the original unit.

A new mercury-boiler design had been developed based upon considerable investigation of comparable steam-boiler experience. It required fewer types of circuits and bends, reducing circulation studies and manufacturing costs. This design fitted nicely between the main building columns at South Meadow. A 29-ft width and 20 1/2-ft depth of furnace were obtained to give the low heat-liberation rate of 18,150 Btu per cu ft at full load. Since the vertical cross section of the new boiler had been established, this fixed the location of the boiler drum 47 ft directly below the original turbine and condenser boiler-room floor.

It was decided to use four 12-in. schedule 80 vapor pipes of SA-280 material for the full-load flow of 1,640,000 lb per hr. This decision was based upon holding 15-psi pressure drop from the boiler drum through the double-disk stop and control valves to the turbine bowl. These pipes also had to be of sufficient length to take care of a vertical temperature expansion of 4 in. with stresses within code limits.

The turbine, generator, and condensers were rebuilt, rewound, and retubed, respectively, and placed in their original positions on the turbine-room floor.

The gravity mercury-return system, which carries the condensed mercury back to the boiler, was designed to have as a part of it a new type sealed sump. This sump, located 9 ft below the turbine-room floor, removes large foreign matter by flotation in a low-velocity section. In addition, by producing a better vacuum in the sump than that in the condenser boiler, a portion of the cascading mercury in the sump is flashed into vapor. This vapor passes through a short connection from the top of the sump to a cooler where it is condensed and run into the system through a trap. By means of this vapor carrier, the light magnesium-oxide dust, which is the only oxide residue in a chemically treated mercury system, is taken out of the returning mercury continuously and deposited in the cooler. The residue formation in Hartford is extremely small because of the all-welded mercury system, bellows-sealed valves, and leakproof turbine-shaft seal. The total air leakage of less than 1 cu ft per hr into the 3000-cu-ft operating vacuum space causes a metallic-magnesium loss in the treated boiler mercury of less than 1/2 lb per day.

Spiral ramps were designed to avoid shock from falling mercury in the gravity-return system. The largest of these ramps was calculated to carry the mercury down 24 ft vertically. The two elements required were to keep the mercury content in the flow circuit to a minimum and to hold the pressure drop within the limited head available. This head had been reduced by the increased boiler pressure of the new unit, which at 130 psi backs the liquid mercury 27 ft up the return line. Only a few feet are left above this to the sump outlet for additional pressure requirements for blowing the mercury safety valves and pressure drop through the return system at full load.

Other items, which were designed to a minimum size, but yet sufficiently large to meet the heat-balance requirements were (1) the water economizer, and (2) the air preheater. For the

economizer, the inlet water was increased 130 deg F over that used in the original unit by additional bleed-heating. A regenerative-type air heater was used instead of the tubular type used in the original installation.

AUTHOR'S CLOSURE

The modern-design fog-type mercury boilers such as the 15,000 kw Hartford Unit are in reality simple boilers offering no serious problems of design and manufacture although somewhat different procedures were necessary as compared to the present-day high-temperature steam generators. Operating problems appear to be quite similar particularly with regard to expansion and other temperature problems.

The problem of burning low-grade fuels may be somewhat more critical with the mercury units because of the higher metal temperatures encountered in the entire mercury boiler rather than in the high-temperature superheaters and their supports only.

As Mr. Weisberg mentioned in his discussion, furnace-tube wastage under certain conditions of coal or fuel-oil operation has been experienced in a greater or lesser degree at both Kearny and

Hartford as has also been the case in certain of the newer high-pressure, high-temperature steam boilers and superheaters.

Corrective measures for this annoying problem are being vigorously pursued with extremely encouraging results already reported from Kearny and elsewhere. Surface coatings of fused 25-20 weld metal as well as likely silicon coatings and paints are now under test in various mercury and steam plants while various tests are in progress using additives in the fuel as corrosion preventives.

Standard design mercury-unit power plants of extremely high over-all efficiency up to 80,000 kw combined mercury-steam capacity are now available for general power applications.

At the present time, only the plants larger than 50,000 kw total mercury-steam capacity require two mercury boilers per mercury turbine although a twin-boiler combination of mercury boilers and turbine may be had if desired in all but the smallest plant sizes.

For example, the new 40,000 kw Schiller Station of the Public Service Company of New Hampshire utilizes two standard-design 7500-kw mercury-unit power plants to supply steam to one 25,000-kw steam turbine.

FIG. 1 EXTERIOR VIEW OF COMMON MUSSEL, MATURE FORM

Some Biological Fundamentals of Marine Fouling

By WILLIAM F. CLAPP,¹ DUXBURY, MASS.

The common mussel is identified as the organism most important in the fouling of sea-water conduits and most difficult to control. Relevant features of its construction, living habits, rates of propagation and growth, and methods of locomotion and self-protection are described. While very young organisms, in general, are less resistant to unfavorable conditions than the mature of their respective kinds, and the mussel is probably no exception; in the case of the young mussel very high resistance is found very shortly after the permanent shell takes complete formation. Chlorination tests on mussels at Kure Beach, N. C., are described and results quoted.

CLASSIFICATION OF FOULING ORGANISMS

THERE are a number of different kinds of marine animals and plants which can be classed as fouling organisms. They can be divided into two important groups; those which are sessile or incapable of further movement after having become attached and those which can become secure or optionally motile. In the first group would be included such common fouling organisms as the barnacles, bryozoans, and algae; in the second, the common mussels and sea anemones.

Those in the first group are unable to escape from an environment which is no longer favorable. Those in the second group

are capable of migrating from an undesirable location and of locating again and becoming firmly attached where the surroundings are more suitable for the support of the organisms.

Among all of the organisms which might be classified as fouling,² the one group which generally appears to be most difficult to control is that of the mussels, typically shown in the mature form in Fig. 1. The various species in this group are frequently able to survive conditions which eliminate other groups of fouling organisms. Therefore the remarks following will be confined to the mussel, and it is believed safe to assume that in so far as organisms which are of real importance in the marine-fouling problem under discussion are concerned, methods or materials which will check fouling by mussels will be at least equally effective in controlling the other organisms.

Among the various species of mussel which are found commonly and plentifully in intake systems, the edible mussel, *Mytilus edulis*, is probably the worst offender. It has a very wide distribution along the Atlantic coasts of Europe and the United States, and also on the California coast. Other common species of fouling mussel are *Mytilus californicus*, *Mytilopsis leucophaea*, *Brachydontes exustus*, and *Brachydontes recurvus*.

USUAL HABITAT OF THE SEA MUSSEL, MYTILUS EDULIS

Mytilus edulis normally lives and thrives in enormous numbers in water with salinities varying between 15,000 ppm and the 30,000 ppm or more of normal sea water, in the between-tide

areas in more or less sheltered harbors and estuaries. The *Mytilus* also thrives, with appropriate conditions of environment, at considerable depths. Individuals may exist in water of lower salinity, but under such conditions comparatively few survive. Therefore those present under conditions of low salinity are so few in number that they contribute very little to fouling.

In harbors where conditions are favorable, *Mytilus edulis* frequently will form great "beds" several acres in extent on the mud flats which are exposed at low water. In these beds mussels of all ages and sizes are fastened together in clusters which may contain hundreds of individuals to the square foot.

While it is true that such mussel beds are also found below the mean low water and even at considerable depths in the open water outside of harbors, it seems probable that the heavy growths of mussels frequently found in intake tunnels are formed by the offspring of the parents living in the mussel beds in the shallow harbor water in the neighborhood of the intake tunnel.

PHYSIOLOGICAL FACTORS AND DEVELOPMENT OF *MYTILUS EDULIS*

The sexes are separate. The female *Mytilus edulis* may produce considerably more than 1,000,000 eggs in a single season. After fertilization, cell division and the development of the free-swimming embryo are rapid. The duration of this development of the *Mytilus* free-swimming larva, up to the appearance of the first embryonic shell, varies considerably. Some investigations have shown that this period of growth may be completed in as brief time as 12 days, while in other cases the same development requires more than 3 weeks. This variation appears to be normal and undoubtedly is due to favorable or unfavorable conditions of temperature and other factors.

During the period of larval development the embryos are not attached, in fact, are not sufficiently developed to have formed any organ which could be used for the purpose of obtaining a foothold. They may be carried back and forth by tides and currents and therefore may be widely distributed. When the embryo has formed the first protective shell it is approximately

0.25 mm in length. The shell is transparent and bears little resemblance to the second protective shell which the animal begins to form almost immediately beneath the original embryonic shell.

During the height of the breeding season these minute embryonic mussels, which have progressed to the shell form, may appear in great numbers on any material which provides a satisfactory foothold. Wooden panels placed in the water during the seasons when these larval forms are abundant frequently show great numbers of individuals which have arrived on the panels and are endeavoring to secure a firm foothold. While such "sets" generally occur during the late spring, summer, and early fall months, the past winter saw unusually heavy sets in December, January, and February, at Portland, Me., Atlantic Beach, N. Y., and other northern locations.

At Atlantic Beach, panels submerged for 30 days ending January 13, 1949, were found completely covered with the shelled embryos of *Mytilus edulis*. Many specimens had attained a length of 1 mm. The average number of individuals to the square inch was found to be more than 1000. Figs. 2, 3, and 4 are greatly enlarged views of mussels from the set at Atlantic Beach. These figures show young mussels in the two stages of development mentioned. The embryonic shell is clearly visible at the umbo of the larger specimens. Fig. 4 is of special interest showing juvenile mussels attached to a hydroid stock. It is possible that unusually favorable conditions during the past winter months have been responsible for the early development of embryo *Mytilus*. It is not known whether or not they are able to survive the unfavorable conditions of subsequent low temperatures and probably scanty food supply.

In the case of the normal mussel, 10 months after having become attached as a minute embryo 0.5 mm in length to any submerged object, an individual specimen of *Mytilus edulis* may grow to be more than 50 mm in length, 35 mm in width and 20 mm in thickness. Thus an individual may increase 1,000,000 times in bulk during a growing period of 10 months. It would also follow that if the majority of such embryos should

live, a pint of *Mytilus* embryos might, in the same period of time, develop into a mass of mature specimens weighing 500 tons or more.

RELATIVE SUSCEPTIBILITY OF YOUNG *MYTILUS EDULIS* TO UNFAVORABLE ENVIRONMENT

From numerous observations it seems certain that under normal conditions embryonic and immature *Mytilus edulis*, rarely more than a few millimeters in size, are responsible for the *Mytilus* fouling in intake tunnels. The system of screens which usually is operated at the entrance of such intakes, would prevent

passage of large specimens, and certainly would prevent passage of individuals large enough to be breeders. Therefore the efforts of those who have attempted to control mussel fouling have been to prevent the attachment and survival of the embryonic and immature individuals which are carried into the tunnel.

It has been generally believed and undoubtedly is true that with all organisms the mortality is highest in the embryonic or immature stages. The mature organism is stronger and better adapted to survive unfavorable surroundings than the very young of the same species. This is probably true also with *Mytilus edulis*. However, apparently in the case of *Mytilus*

edulis a high degree of endurance is attained at a rather early age after acquiring the permanent shell. In certain studies made at the Kure Beach Test Station near Wilmington, N. C., and also in tests conducted by H. E. White,³ the very young of but few millimeters in size of at least some species of mussel are found as capable of surviving under the described unfavorable conditions as the mature animal. At this stage the bivalve shells can be closed tightly for long periods of time, thus completely excluding any obnoxious materials which may be present in the water.

LOCOMOTION AND GROUPING OF MYTILUS EDULIS

The *Mytilus*, like all other mollusks which are provided with such an organ, uses its single foot for locomotion. In young specimens 2 or 3 mm or less in length, the foot, when extruded, is of about the same length as the shell. Near the tip or outer end of the foot is a minute orifice through which the animal is able to extrude a very delicate filament quite similar to the strands of fine spider web. It is this web which provides the first "holdfast" for the immature mussel. By means of powerful muscles the foot can be moved in any direction, lengthened, or contracted at will. The motion of the foot in a mussel which is migrating from one location to another bears a striking resemblance to the motion of an elephant's trunk. When moving, the foot is extended to its full length, the tip end is arched, and the thread-spinning gland is touched to the surface of the material upon which the organism is moving. The thread is firmly cemented in the form of a minute pad to this spot, and it is sufficiently strong to support the weight of the entire animal and shell if suspended in the air. As soon as the thread is attached to the base, the foot is contracted and the shell is pulled forward until it is directly over the new point of attachment. Specimens which are as large as 5 mm in length are therefore capable of moving for a distance equal to the length of the shell at each time a new holdfast is formed. Since each forward movement may require only a few seconds, the total distance covered in an hour may be several feet. With still larger individuals, the length of the foot in proportion to the length of the entire shell tends to be smaller, progress so tends to be slower, and distance covered in a given period of time much less.

When the mussel has reached a spot where conditions are favorable, it remains stationary while the foot, waving around in all directions, exudes a large number of threads, known as the byssus, each of which is firmly cemented to whatever the gland of the

foot comes in contact with and provides an attachment which is exceptionally secure. Fig. 5 is a drawing of a mature mussel showing the foot extended and a number of byssus threads attached. Fig. 6, also a drawing, shows the internal anatomy. Many of the holdfasts may be upon the base upon which the mussel is traveling, or upon the shells of other mussels or other organisms near at hand. The mussels customarily come to rest in large clusters with a mass of weblike holdfasts attached to the base and to each other, as illustrated for small clusters in Fig. 7. When conditions, for one reason or another, become unsuitable, the organism can cut its cables and again endeavor to move on. However, in large clusters it is obviously necessary that all individuals have the same urge to separate one from an-

other and from the base. Tests have shown that complete severing of all holdfasts in a cluster can be and frequently is accomplished in the comparatively brief period of only an hour or two.

There is one other important method of locomotion of which the mussels are capable. Young individuals of 4 mm or 5 mm or less in length are able to sever their holdfasts and float away from their immediate environment. By means of tides, currents, and winds they may in this way be carried for long distances. Having no power to direct their movements, their ultimate landing spot is a matter of chance. Incidentally, during a migration of this type, many individuals up to 4 mm or 5 mm in diameter may be carried through the screens and then manage to secure a foothold in some portion of an intake tunnel or system. It is believed that such small mussels are capable of retaining inside of the shell a small bubble of air or gas which enables them to float at will in the water. If the mussel is disturbed while floating, the bubble disappears and the mussel sinks rapidly to the bottom.

KURE BEACH CHLORINATION TESTS

At the Kure Beach Station studies were undertaken to determine the comparative value of different schedules of chlorination in control of mussel growth. The procedure was to place a test tray in each group of identical weir boxes or compartments supplied with continuously flowing sea water. The general arrangement of the test equipment is shown in Fig. 8. Individual compartments were approximately 8 in. \times 10 in. \times 24 in. long. Turbulence was reduced by a perforated stilling baffle at the mid-length. Water entering the different compartments was chlorinated to selected residual concentrations by automatic feeders on predetermined schedules.

In order to determine the comparative value of various strengths of chlorine in the control of fouling organisms when added to the circulating water for varying periods of time, the following procedure was adopted:

The organisms used was the *Brachydontes exustus*, one of the mussels commonly found in intake systems in southern waters. The normal habitat of this mussel is in the between-tide area, where they grow in such abundance that they frequently completely encrust wharf piling, bulkheads, and other structures in the open sea. The individual specimens can become so firmly attached to steel, concrete, wood, or other materials, that they cannot be dislodged even by the heaviest surf. As in the case of other species of mussel, the young are incapable of attachment to any surface until they have developed to the stage at which the embryonic shell has been formed and the organism has reached a length of 0.25 mm or more.

Clusters of the mussels, containing from 50 to 100 specimens of lengths varying from 0.5 mm to 35 mm, obtained from the between-tide area of a sheet-steel bulkhead, were used in the test. Care was taken not to injure the specimens by rupturing the byssus gland in the foot. By means of a scalpel the byssus threads were cut as closely as possible to the pads on the tip ends of the threads. The clusters were then placed in separate porcelain dishes and the dishes submerged in clean flowing sea water. Within an hour or two the clusters had become sufficiently firmly attached to the extent that they could only be removed with difficulty. At the end of 24 hr the clusters could not be shaken loose from the containers. The dishes were then distributed in the various weir boxes as follows:

- Box No. 1—Nominal chlorine residual, 0.00 ppm...Control
- Box No. 2—Nominal chlorine residual, 0.25 ppm...Continuous
- Box No. 3—Nominal chlorine residual, 0.5 ppm...Continuous
- Box No. 4—Nominal chlorine residual, 1.5 ppm...2 hr on: 2 hr off
- Box No. 5—Nominal chlorine residual, 3.0 ppm...2 hr on: 2 hr off
- Box No. 6—Nominal chlorine residual, 1.5 ppm...2 hr on: 6 hr off
- Box No. 7—Nominal chlorine residual, 3.0 ppm...2 hr on: 6 hr off

It should be stated that the chlorine residuals given in the foregoing table were determined colorimetrically by the orthotolidine method with a disk-type comparator, instead of deter-

FIG. 8 ARRANGEMENT OF EQUIPMENT USED ON CHLORINATION STUDIES, KURE BEACH, N. C.

FIG. 9 CLOSE-UP VIEW OF WEIR BOXES, CHLORINATION TEST EQUIPMENT, KURE BEACH, SHOWING SLIME AT WEIR OF BOX NO. 1, ABSENCE OF SLIME AT OTHERS

mined by the starch-iodide method,⁴ or by the methyl orange method⁵ and accordingly are merely nominal values. It is possible that absolute values in the lower concentrations may have been as much as 100 per cent higher than shown in the tabulation. On the other hand, for comparison with figures secured by the orthotolidine method, of course no correction is required in these tabulated values.

At the end of 24 hr the clusters in the control-weir, box No. 1, with no treatment, were still firmly attached and no noticeable change had taken place. In all of the other weir boxes the mussels had begun to separate from the clusters and many were lying loose on the bottom of the containers with no attachment. At the end of 6 days no change had taken place in the control-weir, box No. 1. The clusters were still firmly attached, and the individuals in an apparently healthy condition. In the containers in weir boxes No. 2 and No. 3, which were being given continuous chlorine treatments with residuals of nominally 0.25 ppm and 0.5 ppm, respectively, the mussels had all lost their holdfasts. The shells of many were opened wide, and when the animal thus exposed was touched with a teasing needle the shells were not closed. The effect on slime-producing organisms from the continuous presence of chlorine in the sea water is shown in Fig. 9, a view of the weirs of boxes No. 1, No. 2, and No. 3, and the absence of mussel activity in water of 0.25-ppm chlorine concentration is shown in Fig. 10. The clusters in weir boxes Nos. 4, 5, 6, and 7 had also severed all attachments, but the majority of the specimens of all sizes had the shells tightly closed. Comparatively few had the shells open.

At this time, the end of 6 days, all of the containers were removed from the weir boxes and were submerged again in clear,

FIG. 10 GLASS PANELS FROM CHLORINATION TEST, KURE BEACH, COMPARING EFFECTS OF CONTINUOUS 0.25-PPM NOMINAL CHLORINE RESIDUAL AND UNTREATED SEA WATER USED FOR CONTROL

untreated, flowing salt water for 24 hr. All of the specimens in control container No. 1 appeared to be alive and in excellent condition. At the end of the 24 hours none of the specimens in containers Nos. 2 and 3 had revived, all shells were widely opened, and disintegration of the animals thus exposed had started. In containers Nos. 4, 5, 6, and 7, all of the specimens were still unattached but many still had the shells tightly closed and only 25 to 50 per cent had the shells open in any of these containers.

It should be noted here that many of the mussels which remained alive in container No. 6 (2 hr chlorination at 1.5 ppm, 6 hr no chlorination) extruded the foot and began to migrate within a few moments after having been submerged in clean salt water. Within 24 hr these individuals had again formed in two

⁴ "Residual Chlorine," Standard Methods for the Examination of Water and Sewage, American Public Health Association, 1936, pp. 164-165, and 228-232.

⁵ "Colorimetric Determination of Free Chlorine With Methyl Orange," by Michael Taras, *Analytical Chemistry*, American Chemical Society, vol. 19, 1947, pp. 342-343.

or three clusters and were firmly attached. This to a lesser degree was true in the case of the mussels in containers Nos. 4, 5, and 7. It was also noted that the very young specimens only 1 mm or less in size were as quick to recover and as agile in migrating as the larger specimens. This would tend to discount the belief that the shelled young are necessarily more susceptible to unfavorable conditions than the older individuals. Once this form has been reached the immature *Mytilus* is soon as resistant as the mature specimen. However, it is probable that the free-swimming larvae, without the protection of the shell, would succumb quickly to such severe conditions.

The mussels in containers Nos. 2 and 3 were discarded, and the dead mussels in containers Nos. 4, 5, 6, and 7 were removed and new specimens were added. The tests were then repeated for 5 consecutive weeks, following the same procedure and with approximately the same results. Since a considerable number of new healthy specimens were added to containers Nos. 4, 5, 6, and 7 at each weekly interval, the maximum period of individual survival under the intermittent treatment was not determined.

SUMMARY OF KURE BEACH TESTS

Continuous chlorination at 0.25 and 0.5 ppm resulted in a complete kill of *Brachydontes exustus*. In addition, no fouling organisms of any kind, or slime film, could be found in these weir boxes.

A varying number, probably averaging 50 per cent, of *Brachydontes exustus* were killed in the weir boxes which were provided with intermittent chlorination. In addition, living barnacles and Bryozoa were found in these weir boxes.

RELATED OBSERVATIONS AND DEDUCTIONS

Some organisms, generally those which are not provided with a protective shell or covering, are much more susceptible to unfavorable conditions than others. Among such organisms the sea anemones and hydroids probably belong. It is of importance in this connection to note that blocks of wood which were placed in the control weir box at Kure Beach Station were destroyed by teredo in a few weeks. Similar blocks placed in all of the other weir boxes showed no trace of any borer attack. It is evident that the embryonic teredo without the benefit of any shell for providing protection is unable to survive any of the

chlorine dosages used during this test. On the other hand, once having succeeded in entering the wood, the mature form of teredo would be well protected against all but the most severe unfavorable conditions.

Those marine mollusks which are accustomed to living exposed in the between-tide area are frequently provided not only with strong shells which can be closed very tightly, but also with very powerful muscles which enable the animals to keep the shells tightly closed for long periods of time. The scallops and mussels are of this type while the various species of burrowing soft clams, which are protected by the burrows they live in, frequently do not have tightly fitting shells or strong muscles for closing them.

The mussels living on our tidal flats are out of water and exposed to the rays of the hot sun during the summer for 2 hr or more during each low-tide period. For them to survive, it would be essential that they protect themselves by keeping the shells tightly closed during the period of exposure. It would appear to be a necessary adaptation. It would seem probable that the *Mytilus*, which can remain closed and survive exposure to the air and hot sun for 2 hr each day, could survive equivalent unfavorable conditions in an intake tunnel for equal periods of time.

It would seem from the tests described that continuously but comparatively slightly unfavorable conditions would eliminate the undeveloped and unprotected embryos of the fouling marine organisms. This would be the most desirable objective to attain. It would also seem that much more unfavorable conditions are necessary to produce a kill when the organisms have passed from the embryonic stage to the mature form.

On the other hand, the evidence seems to indicate that, with some *Mytilus*, even slight and intermittent chlorination would result in the mature specimens releasing the holdfasts. In this way it is conceivable that, if still small, they might then be carried through the system without causing further trouble. However, it is also possible that with sufficiently low velocities this might result in an accumulation on the bottom of the tunnel which, eventually, would have to be removed.

ACKNOWLEDGMENT

The author desires to express his appreciation to Mr. Frank L. LaQue of The International Nickel Company, for permission to reproduce the illustrations of test equipment used at Kure Beach Station, and to quote from results secured.

FIG. 1 ARRANGEMENT OF INTAKE TUNNEL, ELECTRIC GENERATING STATION

Project Study for the Mitigation of Marine Fouling

By I. A. PATTEN,¹ LYNN, MASS.

The growth of marine organisms with resultant fouling of aquatic vessels and tunnel structures, throughout the years, has presented the utility engineers with a problem the effect of which creates lower efficiencies and higher maintenance costs. Mitigation of such growth and fouling on several occasions has been studied by industrial engineers and biologists. The result of such studies indicates *Mytilus* are the most difficult to control. The paper is a résumé of experiments and the development of a chlorine program which to date has proved effective and economical.

INTAKE-TUNNEL ARRANGEMENT

IN the year 1927, fully realizing the necessity of expansion to meet the future supply of electricity, the Lynn Gas & Electric Company, Lynn, Mass., entered into a construction program the ultimate objective of which was to provide an additional 60,000-kw capacity. This entire development was to be housed in a new structure adjacent to the old generating station.

¹ Superintendent, Lynn Gas & Electric Company.

Contributed by the Power Division and presented at the Spring Meeting, New London, Conn., May 2-4, 1949, and the Semi-Annual Meeting, San Francisco, Calif., June 27-30, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society. Paper No. 49-8-20.

Included in the new development was a reinforced-concrete intake water tunnel for condenser-cooling purposes. The tunnel as designed provided for one concrete rectangular tube, 7 ft square near the intake and of progressively decreasing cross section, approximately 250 ft in length, as shown in Fig. 1. The intake end on the Lynn Harbor front, submerged to minus 13 ft relative to mean low-water datum, is equipped with inner and outer gates which permit unwatering and cleaning either screen well without interruption of service. The new tunnel, however, is a single-tube conduit; consequently, when tunnel cleaning becomes necessary, it can be accomplished only by shutting down the main tunnel and employing inadequate by-pass connections for circulating-water requirements. The maximum demand for total cooling water at this station is in the order of 9400 cfm. Due to the design and location of the suction chambers in the tunnel, the velocity of the water varies in its flow, but for all practical purposes the maximum rate is around 3 fps.

EARLY FOULING PROBLEMS—EQUIPMENT OUTAGES

The new station was put into operation in the fall of 1929, and, following approximately a year of satisfactory operation, condenser fouling due primarily to mussel and marine growths occurred. Within a relatively short time condenser outages were becoming very frequent, thus necessitating search for the cause of this trouble. A diver was sent into the tunnel to determine the marine-growth condition existing therein, and much to

the surprise of all concerned, a very heavy congestion of *Mytilus* (common mussels), *Tubularia* (sea moss), and *Metridia* (sea anemone) was found. These growths were firmly attached to the walls and roof of the tunnel and varied in amounts fairly consistent with the rate of flow; that is to say, the nearer to the intake, the more plentiful the attachment of the wall surfaces.

Now the handwriting was on the wall, so to speak, the operational problem of "condenser fouling" had a brother—"tunnel congestion," and these two factors were of grave concern as time passed.

It was a frequent occurrence for each turbine generator to be out once a week for condenser cleaning, and the deposits of slime, silt, and mussels in the tubes were very disheartening. The economics of such conditions in a modern generating station were embarrassing as outages necessitated purchasing power from a nearby utility, and operating efficiency was far below normal, primarily due to poor vacuum conditions in the turbine units.

MANUAL REMOVAL OF FOULING COSTLY

In the spring of 1931 it became necessary to unwater the tunnel and to do a thorough cleaning job, which was termed at the time the "clamming" expedition. This resulted in the removal of approximately 160 tons of mussels and other marine growths. Accompanying the marine growth, there was an accumulation on the floor of the tunnel to a depth of 18 to 24 in. of harbor silt, mussel excretion, and many dead-mussel shells.

From Fig. 1 it is obvious that an undertaking of this kind was costly and difficult to perform, as all debris must be raised from the tunnel through four manholes throughout the length. The temporary suction line was attached to the station's largest turbine generator (25,000 kva) and the deficiency of kilowatts was supplied from an adjacent system. The time consumed was approximately 20 hr, and the cost in the vicinity of \$6000 for equipment and labor. Yet, a tunnel-cleaning program had to be established for at least once every 12 months. The reality of this problem, plus the headache of condenser cleaning, the loss of station efficiency, and the accompanying high operating maintenance cost were factors which led to vigorous study and investigation of the mitigation of marine growth by means of agents not then too familiar to the utility industry.

INITIAL INVESTIGATION AND OBSERVATIONS

The investigation was begun by correspondence with other utility companies and a few industrial plants to gain knowledge of their experience. In a few cases, chlorine was mentioned favorably even though very little information was available that could be applied directly to the complete elimination of mussels by chlorination. The Department of Commerce, Bureau of Fisheries in Washington, supplied information relative to the spawning of mussels which they stated should cease about the first of August but added the cautionary comment that the free-floating larvae would exist in abundance for at least 2 weeks after the end of the spawning season and might be expected to attach themselves within the intake system during such period. They also advised that the use of chlorine gas for preventing the growth of mussels was being investigated by the Bureau.

During the interim two interesting facts were learned. The first was that the Atlantic seaboard during the seasons of 1930 and 1931, had produced what was termed in those days abnormal mussel years. While it seemed within reasonable prospect that future years would be more favorable, there still also seemed sufficient room for pessimistic doubt to warrant continuance of the investigation. The other, which was felt in part directly responsible for the mussel conditions in the immediate area, was the changed sea-water condition in Lynn harbor.

Up to 1929 the Lynn sewerage system had been flowing directly into the harbor, resulting in a fairly high concentration of pollution in the water. Subsequent to 1929 an outfall sewer system was laid, and the sewerage pollution was removed from the harbor waters, which was favorable to marine growth.

INITIAL TRIAL OF CHLORINATION

Further study, including reference of the problem to our engineers and to one of the country's most noted marine biologists, led to a decision to try chlorine as a preventive against mussel development. The equipment then available was not too elaborate or complete, and the installation and operation were equally in question as this process was still in its infancy. However, a voluntary committee was formed and, securing what equipment there was available, an operating schedule was set up on February 23, 1931. The recommended and trial cycle of operation consisted of $7\frac{1}{2}$ to 15-min injections once every 3 hr with a chlorine residual 0.4 to 0.8 ppm.

After a few months of operation there was found to be little if any improvement in the mussel situation. This, coupled with the fact that corrosion-erosion of condenser tubes and graphitization of condenser water boxes were noticed about the same time, aroused serious doubt as to the advisability of continuing chlorination. However, persistency prevailed and, in our endeavor to overcome these corrosion conditions, zinc plates were installed in the water boxes, ferrule extensions applied at inlet ends of condenser tubes, and the water-box surfaces treated with hot Apexior.

While these measures offered relief, it was apparent that they should be termed at best deterrents rather than cure. Chlorination was continued until May, 1932, and then discontinued, as everyone felt the objective, mussel mitigation, had not been reached and its attainment uncertain. While all felt chlorine had not failed completely, its continued use seemed unjustifiable until many of the unknown factors had been given further study and evaluation.

CORROSION NOT CAUSED BY CHLORINATION

Subsequent to discontinuing chlorination, the following became apparent:

1 The corrosion-erosion within the condenser tubes was being caused primarily by free oxygen in the circulating water, and the same cause seemed the primary factor in the attack on the ferrules, tube sheets, and water boxes. Tests showed that a considerable amount of entrapped air existed in our intake tunnel. This air, when passing through the circulating pumps and thence into the condenser, resulted in the liberation of large quantities of free oxygen. The first preventive step was to install a vent standpipe about midway of the intake tunnel. This procedure immediately showed favorable effects and was followed by installing air erosion eliminators in the condenser water boxes, in addition to the vent.

2 Stray-current electrolysis was also an important factor in the observed corrosion. In the process of investigation, tests were conducted for electrolytic action which discovered evidence of stray currents prevailing not only upon the condensers but the pump impellers and associated equipment. Preventive measures were taken, and it was soon learned that the foreign current extended out into the screen well and forebay. Finally, an open negative was discovered on an adjacent direct-current system ground submerged in the Saugus River. When repair to the negative was effected, the electrolytic condition was eliminated. These facts are mentioned to indicate how our thinking changed with reference to the effect of chlorine on this type of equipment.

ELECTROCUTION ATTEMPTED

One other experiment, worthy of mention in passing, was an attempt to electrocute various types of marine growth. Two framed wire grids were submerged in the forebay several feet outside the screen well. Low-voltage electric current was supplied to one grid and no energy to the other. The grids were withdrawn monthly for examination. The energized grid contained few if any mussels, and other types of marine growth, such as barnacles, etc. On the unenergized grid quantities of mussels and other marine growth were present. It seemed probable at the time that electric energy supplied through a properly designed screen or grid system of some kind would result in killing the mussels when in the embryonic or larval stage. However, due to lack of available equipment, after about 5 months of operation, the experiment was discontinued without actually determining the merit of the scheme.

DECISION TO RESUME CHLORINATION

From 1932 to 1944 little was accomplished in mussel mitigation, and the tunnel cleaning continued once each year. The season for cleaning was changed from spring to fall, however, and fall cleaning proved much more satisfactory than spring cleaning, that is, the tunnel was cleaned after the fall spawning season, say, in October, consequently eliminating a large proportion, by volume at least, of the mussels by not permitting them to remain in the tunnel and develop during the winter months. The majority of mussels then to be removed, consisting primarily of the current summer's breeding, were much smaller in size.

These last 10 years or so the clamming business was becoming tiresome, especially without a market for the product but, with renewed hope from several biologists, another vigorous attack was begun on the investigation and control of marine growth.

In June, 1945, thorough study for the elimination of marine growth, *Mytilus* especially, was resumed. All phases of the intake-tunnel conditions and condenser operations, all tests, and previous experiments were reviewed and analyzed. Several of the previous experiments were found inconclusive in the light of development and research through the intervening years, and a new tentative program finally was agreed on. Chlorination was decided upon as the weapon, and the greatest problem was the cycle of operation; intermittent chlorination with high residual, or continuous chlorination with much less residual. The burden of opinion from our consultants was in favor of intermittent chlorination. Accordingly it was decided again to try chlorine with intermittent injection. The installation of needed equipment was completed in November, 1945.

FOULING TEST PANELS

About this same time an investigation was undertaken to secure information on the current natural rate of marine fouling by the aid of a series of test panel boards, each 6 in. \times 12 in. and $\frac{1}{8}$ in. thick of black plastic composition, five of which were continuously active. The test panels were submerged within 3 ft of the bottom of the forebay and 5 ft in front of the intake tunnel at the rear of the screen house. Four of the test panels in use were given numerical identifications and the fifth serving as a control was designated X.

After the submersion of the test panels for 1 week, one of the numbered panels and the X control were removed and immediately wrapped with care in paper towels and sent to the biological laboratory for analysis. This was done on Monday of each succeeding week. A data sheet accompanying the panels listed tidal condition, sea-water temperature, and location from which the test panels were removed. After the first month, each numbered test panel should give a sample representative of potential

fouling development in the previous 4 weeks for comparison with the latest single week's record of the X-control panel.

Later in 1946 a test station was added about mid-length of the tunnel, directly in the flow of the chlorinated sea water to indicate the chlorination results. Test panels of different types of material including clear lucite and reinforced cement were tried, and Plexiglas supporting rods in place of flexible supporting cables. Widely varying results obtained from these panels led to the conclusion that they were not giving dependable indication of tunnel-fouling conditions.

CHLORINATION RESUMED

On November 3, 1945, the intake tunnel had been thoroughly cleaned. Chlorination on hand control was started November 4, 1945. Under this first schedule, from November, 1945, to April 3, 1946, chlorine was injected 1 hr, twice daily at 0.2 ppm residual. On April 3, 1946, time-clock automatic control was installed, and the chlorine-injection cycle was changed to 30 min each 8 hr with residual at 1 ppm. After 1 month of operation on this program, it was decided to increase the residual to 2 ppm and this was continued until about October 1, 1946.

On October 24, 1946, with approximately 1 year of experience with chlorination, the tunnel was inspected by a referee committee and subsequently cleaned. As compared with previous years, approximately as many mussels in number were found, but the average size was considerably smaller. The belief of all present was that, while chlorine had been instrumental in limiting the growth, it apparently had in no way affected the number present and adherence of the mussels to the walls of the tunnel. *Tubularia* and *Metridia*, on the other hand, had decreased materially.

Definite information was not available on how long a mussel can exist with the shell completely closed, without oxygen. Our biological consultants expressed belief that such a condition might prevail for many hours, and recommended longer periods of chlorination at lower residuals. This raised the question that if the length of the chlorine-injection period was increased sufficiently, what was the minimum residual concentration at which mussels could be killed.

From operating experiences and indecisions, the committee again conferred to determine whether or not sufficient improvement had been gained to warrant further experimental work and retention of the chlorinating equipment. From this conference the following was agreed:

- 1 Chlorination had brought no adverse results on condenser tubes, water boxes, or pump impellers.
- 2 *Tubularia* and *Metridia* had been practically eliminated from the tunnel, screen well, and suction chambers.

Even though the mussels were as numerous, they were smaller in size and apparently not so firmly attached to the surfaces. The chlorine plant had operated efficiently and satisfactorily. Thus, weighing the results, decision was reached to continue for another 12-month period. It seemed beyond doubt that by so doing operations would be improved, and the economics would justify chlorination, as materially better vacuum was then being secured owing to cleaner condenser tubes and less fouling of condensers.

PILOT TUNNEL

During the winter of 1946-1947 further efforts were made to determine the seasonal changes which should be made in the chlorination schedules to compensate for changes in water temperature and spawning season. System-load conditions prevented frequent inspections of the main tunnel. This, together with the misleading indications given by test panels, prompted

FIG. 2 PILOT TUNNEL AT INTAKE SLIP

the construction of a miniature tunnel which would allow as frequent inspections as desired. The pilot tunnel, which is shown in Fig. 2, is an exact reproduction of the main tunnel constructed on a scale of 1 to 7. Overflow ports of identical shape and proportions simulate entrances to the suction chambers of the various machines in the main tunnel. Water from the forebay is pumped through the pilot tunnel continuously, and chlorine is diffused at the same proportionate rate as used in the intake tunnel. In other words, chlorinating programs for the main and pilot tunnels are identical. Removable covers were installed at the top and end of the pilot tunnel, providing for intermittent inspection of inner surfaces of the tunnel.

In June, 1947, water was fed initially through the pilot tunnel and, from its subsequent inspections, establishment of more definite ideas relative to chlorination cycles and residuals became possible. In the section of the tunnel nearest the intake, which was designed to operate without chlorine injection, mass distribution of the mussels was obviously in inverse relation to local velocities, much as observed in the intake wells of the main tunnel. When chlorination was started in the pilot tunnel there had accumulated in the wooden discharge trough a considerable growth of sea moss and marine organisms which disappeared within a few days after chlorination.

PLANKTON NET

Coincident with operation of the pilot tunnel, an attempt was made to employ the Plankton net for trapping live organisms, the trapping equipment used consisting essentially of a closely woven silk sleeve of conical shape with a 6-in. opening at the entrance and a $1\frac{1}{2}$ -in. opening at the other end to which a sampling bottle is attached. Results were unsatisfactory even with the aid of a metal frame and rudder to hold the net submerged and parallel to the water flow. Very few mussels were trapped, although more numerous present as evidenced by infection of the pilot tunnel 20 ft away. No doubt the difficulty was due to the low velocity of flow in the forebay as such equipment has been effectively used at higher velocities.

THERMAL TREATMENT

Early in 1947 consideration was given to temperature treatment by steam or hot water for mussel elimination. The conclusion reached was that the procedure could be made effective

FIG. 3 EAST SIDE WALL OF TUNNEL, JULY 20, 1947

and, in some instances, possibly economical but, with the single main intake tunnel and the system demands, it was impractical for Lynn Station. Consequently the idea was abandoned.

INTERMITTENT CHLORINATION CONTINUED

On June 8 and on July 20, 1947, the main tunnel again was inspected by the referee committee and in comparison with inspections of October and November, 1946, a considerable area of concrete surface was visible, and the small clusters of mussels were scattered as shown in Fig. 3, taken on July 20, 1947. This was encouraging, as the previous inspections in the fall of 1946 showed continuous blanket formations from 2 in. to 4 in. thick on the walls as shown in Fig. 4 taken November 16, 1946. For

future inspection comparisons, all metal and tunnel surfaces were zoned and their observed conditions recorded.

Questions raised from this 1947 inspection were as follows:

- 1 Why are certain areas free from mussels and other areas infested in such varying degrees?
- 2 Were chlorine diffusion nozzles designed properly to prevent streamlining of chlorine?
- 3 Due to irregularity in surface areas in concrete, did "water slip" lower chlorine concentration on the wall surface?
- 4 Are the survivors the "supermen" of the mussel family or is our chlorine program improperly designed?

These questions among others have been studied by H. E. White.²

Continuing the tests and tunnel examinations during the summer months of 1947, it was naturally gratifying when the November cleaning produced only 16 tons, compared with 107 tons in 1946, and 331 tons during 1945, as shown in Fig. 5. However, complete control was the goal sought, and anything short was not considered satisfactory; consequently, chlorination was continued during the winter of 1947-1948, on the basis of 30 min each 8 hr at 0.75 ppm residual.

November, 1947, being the second anniversary of the chlorine equipment, the question of its continued use had again been considered. Favorable factors included progress in mussel control, no further signs of corrosion-erosion of condenser and related equipment, reduced maintenance costs for condenser fouling, and cost for chlorine consumption had not exceeded the estimate. The single unfavorable factor was lack of full mussel control. The decision again was favorable for retaining the chlorination equipment.

² "Control of Marine Fouling in Sea-Water Conduits Including Exploratory Tests on Killing Shelled Mussels," by H. E. White, published in this issue of the Transactions, pp. 117-126.

FIG. 5 TONS OF MUSSELS REMOVED ANNUALLY FROM INTAKE TUNNEL

On April 25, 1948, tunnel conditions were found about comparable with November, 1947, after cleaning. The few mussels present were small, ranging in size from 1 to 5 mm at approximately 2 to 5 per sq ft of area, even though chlorine injections were only three 20-min periods each 24 hr at 0.75 ppm residuals. On the other hand, elimination of mussels was not complete.

Decision was in favor of continuous chlorination at 1 ppm residual which was at once put into effect.

CONTINUOUS CHLORINATION

On June 27, 1948, after tunnel inspection which showed favorable results, a program of continuous chlorination at 0.5 ppm residual was set for the balance of the 1948 recognized propagating season, or until water temperatures dropped to 40 F, unless future inspections of the pilot tunnel indicated the necessity for change. Immediately after the inspection, new dual diffusion pipes were installed in one screen well at the tunnel intake, and apparently they are a decided improvement over the single diffuser.

The main tunnel was opened approximately each 6 weeks for the balance of the season, and results continued satisfactory. As shown in Fig. 6, the last seasonal inspection was made on October 17, 1948. All of the referee committee present agreed that a

of the tunnel. Grouping of large mussels is visible only near the base of the wall. The remainder of the wall and roof in this vicinity is devoid of any fouling.

FIG. 6 EAST WALL OF INTAKE TUNNEL NEAR INLET, OCTOBER 17, 1948, SHOWING BARE CONCRETE AFTER FULL SEASON OF OPERATION

decided improvement existed. Mussels where present were, in general, widely scattered, many wall areas completely void of any marine growth, mussels present were of miniature dimensions—some very small yet with completely formed shell. Attachment to the walls was rather weak with, it seemed, fewer byssus threads, while on the floor almost all the mussels were dead. From visual summation it was estimated, if the tunnel was thoroughly cleaned, the maximum in weight of all types of marine growth and silt would not exceed 2 tons, largely concentrated in the relatively less active north end of the tunnel where chlorination had not been continuous. Because of this small extent of the fouling, we decided not to clean the tunnel.

The view of the tunnel interior given in Fig. 6 is representative of the east side wall in the continuously active zone, photographed October 17, 1948. The man is standing in 3 to 4 in. of water about 20 ft from the inlet end of the 7-ft-square section

FIG. 7 CLOSE-UP OF EAST WALL, MID-LENGTH OF INTAKE TUNNEL, OCTOBER 17, 1948
(Black and white scale divisions approximately 1 in.)

FIG. 8 CLOSE-UP OF WEST WALL, MID-LENGTH OF INTAKE TUNNEL, OCTOBER 17, 1948
(Black and white scale divisions approximately 1 in.)

Figs. 7 and 8 show at close range views typical of the general area of the east and west walls, respectively, about 110-120 ft further from the inlet end of the tunnel where mussels were found in numbers of 1 and 11 per sq ft. Chlorine effectiveness observed in the main tunnel was reproduced closely in the pilot tunnel where walls in contact with chlorinated water were almost

completely free from fouling attachment. Contrast of areas respectively ahead of and following the point of chlorine introduction in the pilot tunnel is rather strikingly brought out in Figs. 9 and 10, views of the interior taken on October 20, 1948.

SUGGESTIONS

From the experience at Lynn Electric Generating Station the following suggestions are offered to those who have or are anticipating marine-growth control in forebays, tunnels, suction pipes, or other aquatic structures:

- 1 Acquire thorough familiarity to the last detail on items such as water analysis and water temperatures, especially during seasonal changes.
- 2 Determine as accurately as possible the hydraulic conditions and variants, including velocities in the structures in question.
- 3 Determine as accurately as possible the metallography of all equipment in the plant through which this water will pass.
- 4 Study as accurately as possible the amount of expenditure created directly by marine fouling in the plant equipment. There is now sufficient information available which at least will give a fair indication of the cost of elimination. In turn, this should establish wherein the economics of the problem lies.
- 5 Do not be impatient. Remember that the price of success is eternal vigilance, and problems not too readily solved are always to be expected.

CONCLUSIONS

In conclusion, the following are believed factual to at least the present degree of success attained at the Lynn plant:

- 1 Chlorine to the extent and magnitude of actual usage has not caused deterioration of condenser tubes, water boxes, pump impellers, or associated equipment although condenser tubes are of various alloys and makes.
- 2 Even in the days when success of marine-growth elimination by chlorine seemed doubtful, benefits were realized due to elimination of slime film on condenser tubes, which resulted in better vacuum and saving in the coal pile.
- 3 As the trial programs have progressed there have been direct and appreciable savings in labor for condenser cleaning, readily evaluated.
- 4 For the year 1948, what can be safely termed operating savings, which consist of avoiding the intake-tunnel cleaning, fewer condenser outages and cleanings, higher vacuum with a resultant reduction in coal usage, have been summarized, giving estimated gross operating savings of \$20,000. Deducting from this the gross operating cost of the chlorine plant, the direct cost for chlorine purchases, interest, taxes, and depreciation on the chlorine plant, the estimated net saving for the year is about \$12,000. It will be noted this estimate has been made on a conservative basis, applying only the recognized and tangible savings, and not including other variables which might be included by thorough analysis.

The author wishes to express his appreciation to Dr. William F. Clapp, his assistant Mr. Peter Richards, Dr. Louis W. Hutchins of Woods Hole Oceanographic Institution, Messrs. R. B. Martin and S. H. Newland of Wallace & Tiernan, and Messrs. E. B. Powell and H. E. White of Stone & Webster Engineering Corporation. Without their able assistance and determination we could not have succeeded to the present degree of mussel and marine-fouling control. While we shall continue to strive for perfection, even though we fall short, we feel assured that satisfactory operations can be continued and with a reasonable degree of economic success.

Control of Marine Fouling in Sea-Water Conduits Including Exploratory Tests on Killing Shelled Mussels

By H. E. WHITE,¹ BOSTON, MASS.

Hundreds of tons of mussels may accumulate in the circulating-water tunnels of a large seaboard power station in a single season. Explicit practical procedures have been determined for meeting this problem by complete extermination of fully shelled mussels by chemical treatment, moderate temperature elevation, or combination of both. General results have broad application. Exploratory tests have demonstrated great practical influence of very moderate changes in temperature of the sea water in extermination of mussels. Any elevation of temperature reduces the required consumption of chlorine, which has been the usual killing agent. For plants with suitable arrangements and load conditions, it appears practical to achieve positive control of marine fouling in tunnels without chlorine or other chemicals by periodic increase of sea-water temperature to not more than 95 F for northeast coastal plants. Numerical results of various treatments as observed in the exploratory tests are summarized by charts.

CONDITIONS WHICH LED TO PROJECT

MARINE fouling develops at such a rate at some coastal sites that it can become a major factor in design of the circulating-water system of a steam-electric power station. In the absence of suitable control treatment, hundreds of tons of mussels may accumulate in the tunnel system of a large power station in a single season. Similar conditions arise in connection with sea-water systems of industrial plants. Even where some degree of control has been employed, accumulations of mussels have reached serious proportions. In some cases complete plant shutdowns have been required periodically for scraping and digging out mussels by hand labor.

With high plant investment and heavy demands for output and continuity of power supply, shutdowns for cleaning tunnels become increasingly objectionable. Continuous 100 per cent cleanliness of tunnels is desired in some plants to avoid periodic cleaning, though the normal intervals between cleanings may be several years. This view is prominent particularly (1) where tunnels are long, (2) where access is difficult, and (3) where labor conditions are unfavorable.

OBJECTIVES OF STUDIES

The objectives of the present project were to determine, if feasible, a practical procedure for control of marine fouling which would give full assurance of 100 per cent extermination at will, under severe conditions with minimum chlorine consumption, and

also, to determine the limitations of control treatments. Divergent opinion on questions of detail left no alternative but to make detailed observations. The specific objective, therefore, was to determine practical procedures which would give positive control of marine fouling based on more specific quantitative observations of actual results of treatments than had been available.

SCOPE OF INVESTIGATION

This paper relates particularly to control of marine fouling where sea water is used for cooling purposes. The primary emphasis is placed on extermination of shelled mussels because, as discussed later, these mussels are commonly the most troublesome element of fouling in circulating-water tunnels of power stations along the East Coast. Somewhat similar conditions are found on the West Coast. Results were needed as soon as possible; hence, although refined methods of tests were laid out, lack of time prevented adoption of most of these in the exploratory tests. The test procedures adopted are believed, nevertheless, to be adequate for the immediate engineering purposes.

OBSERVATIONS IN OPERATING PLANTS

In order to take full advantage of existing experience, personal inspections were made of circulating-water systems of power stations on the East Coast where fouling control treatments were in use, and results appeared reasonably satisfactory. Chlorination exclusively had been used at these stations. Continuous chlorination had been used in a few stations, but all tunnels which were available for internal inspection had been treated by intermittent chlorination.

While treatment had brought great improvement in all cases examined, nevertheless, in the tunnels which could be inspected visually, shelled mussels were found in various quantities regardless of the treatment, even where control treatment was applied conscientiously. In some cases, mussels reached 1½ in. in length. At a southern plant which had reported most successful control of mussels, it developed that the so-called "mussel" was an entirely different organism, which was much less resistant to killing treatments.

Fouling growths were removed by periodic manual cleaning. At one of the stations, fouling in the circulating-water tunnel had become so objectionable to the men who were to clean it that serious labor trouble was barely averted.

Various contingencies were found to occur which would permit mussels to enter and make attachment within the tunnels, for example:

Commercial shortage of chlorine temporarily interrupting chlorination.

Mechanical damage to chlorination equipment or piping, due to accident or unusual conditions such as a hurricane.

Deterioration of screens at the inlet of the circulating-water system from corrosion.

Wear of traveling-screen chains, resulting in sufficiently large openings between panels to permit passage of shelled mussels.

In all tunnels inspected, mussels were observed to attach in

Contributed by the Power Division and presented at the Spring Meeting, New London, Conn., May 2-4, 1949, and at the Semi-Annual Meeting, San Francisco, Calif., June 27-30, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-S-12.

greater numbers in corners between side walls and floor and roof, and in corners following a sudden enlargement of the cross section of the waterway. Any crevices or cracks in the flat surfaces afforded anchorage for mussels even where neighboring smooth surfaces of the wall were entirely free of mussels.

In the course of the investigation special equipment and technique were developed for sampling the sea water at a roof corner of the straight run of a main tunnel during normal commercial operation, in order to determine the reason for accumulation of mussels in corners. Prompt determination of residual chlorine showed full concentration at this location, even with intermittent chlorination, whenever chlorine was being fed. This suggested that the conformation of walls at the corners was more favorable for secure attachment of the mussels.

Another observation which seems of general application was that mussels occur in various arrangements: (1) In the absence of control treatment, all mussels are closely spaced. (2) If diffusion of chlorine is not uniform, localized accumulations occur. (3) Where control is partially effective, arrangements of mussels on the walls, generally develop in the following sequence after cleaning: initially, as individual scattered mussels; then, small groups; later, larger clusters; and, finally, continuous mats of mussels. Continuous mats of mussels may grow to a thickness of about 6 in. before tearing away from the wall and falling to the floor. The process is repeated and more fall to the floor. There they may form a stationary obstruction to the flowing water until removed manually.

Adhesion of clusters of mussels to the walls, in one instance, was found so strong that it was barely possible to pull them off with the fingers without use of metal scrapers. Under such conditions it seemed improbable that a brief application of any water velocity commonly used in a power-station tunnel would detach the mussels. The individual threads secreted by the mussels for attachment are comparatively strong, but the effective strength of the attachment of a cluster results from the great number of interconnected threads used by the group.

In most stations the object of fouling-control treatment was to kill the mussels when very young and most vulnerable, before they had developed shells. Tremendous numbers of these tiny young mussels, only a few hundredths of an inch in length, enter through the meshes of the usual screens during the summer season. Small shelled mussels would pass readily through the screens also. With the usual intermittent chlorination, attachment could be made between treatments.

Although the usual methods for fouling control resulted in great improvement, it was not apparent that any treatment in use in the stations where intake tunnels were inspected, could be relied upon to kill mussels with fully developed shells. Methods which appeared reasonably satisfactory at one site appeared inadequate when applied under other conditions.

From the observations of the survey it was concluded that where 100 per cent cleanliness is required under the ordinary conditions of practical operation, methods of control must be used which would kill shelled mussels and provide satisfactorily for their removal from the system.

GENERAL TEST PROGRAM

As correlation of field observations was not clear, it appeared that possibly some factors had not been evaluated fully. Uncertainties in attempting to apply results of the plant inspections to conditions at new sites, where full reliability and 100 per cent killing were desired, seemed to necessitate more detailed observations to answer conclusively immediate and essential questions. Tests on full-size circulating-water systems were of course desirable but were impractical at the time, not only from the viewpoint of attendance and expense involved, but also because the extensive

trial of new methods in commercial plants involved risk of more frequent shutdowns for cleaning. Therefore the possibility of testing at a small scale was reviewed.

The potential difficulties of reproducing natural conditions for maintaining mussels on a laboratory scale were recognized fully. However, to proceed effectively with the development of fouling-control treatment, it was essential that it be based upon the characteristics and protective measures of the individual mussel. These could be observed much more accurately in small-scale tests, if natural conditions could be simulated sufficiently well.

Uncertainty may arise in making observations in full-size circulating-water tunnels of power stations because small mussels may enter through the meshes of the screen, so that the time during which a given group of mussels has been subjected to treatment is uncertain. With intermittent treatment, mussels may move considerable distances along the interior walls of the tunnel during the intervals between inspections. Therefore, when the number of mussels in a particular zone changes, generally it is not known whether some have been killed, whether mussels have merely changed location, or whether some have been replaced by new mussels which have recently arrived. In small-scale tests, on the other hand, a fixed number of mussels can be kept isolated in separate receptacles and the period of treatment given each mussel may be determined definitely.

With small-scale tests, radical changes in control methods may be tried, because there is no need to proceed cautiously, as might be expedient in commercial stations. Hence, at least approximate results should be expected more quickly.

It had been concluded from inspection of plants in actual operation that the most resistant fouling organisms in circulating-water systems along the East Coast were the common mussel² and the barnacle.³ Also, these appeared to be important elsewhere. At stations where these organisms had been brought under control by chlorination, other forms of fouling became insignificant. Barnacles commonly do not grow to great thickness and hence, are not a direct source of difficulty in large tunnels. Therefore, study was concentrated on the common mussel.

Since no other quick approach to the general problem was immediately available, small-scale tests were attempted. The first step was to develop suitable procedure and then to determine its feasibility. When this had been demonstrated, tests of killing treatments were started. The project was continued except for minor interruptions for some 2 years, 24 hr per day. Several tests ordinarily were in progress simultaneously. Thus at different times, hundreds of mussels have been observed, not as masses of fouling, but as individuals, twice a day, often many more times, until dead.

INITIAL TESTS ON FEASIBILITY OF SMALL-SCALE TESTS

Maintenance of the mussels under reasonably normal conditions proved more successful in the small-scale tests than anticipated.³ Undoubtedly, further observations will dictate modification of details, but results have seemed reasonably consistent. In general, the mussels under test behaved similar to those in the tunnels. With minor exceptions, the specimens remained in groups and clusters as normally. The results in one test tray are shown by photographs.⁴ Fig. 1 shows the initial arrangement of the clusters maintained 2½ weeks after starting. Clusters had been formed and secure attachment made within one day of starting. Fig. 2 shows the conditions 6 weeks after placing the first specimens in the tray. No deaths had occurred. The final locations of the clusters are practically identical with the original, although the individual specimens had moved within the clus-

² Identified technically as *Mytilus edulis* and *Balanus*, respectively.

³ Detail procedure described in Appendix.

⁴ Photographs were taken after removing water from the trays.

FIG. 1 LIVE MUSSELS IN TEST TRAY AFTER 2½ WEEKS

ters and even transferred from one to another. Two specimens wandered away and started to climb the side wall, but did not continue to the water line as customarily occurs when the condition of the water is unsatisfactory to the mussels. Attachment of the mussels was still firm after 6 weeks.

To illustrate the strength of attachment of the mussels, the entire tray was lifted by grasping the central cluster of mussels by the fingers. The weight lifted was 2¼ lb which was considered satisfactory for mussels of this size when maintained by batch replacement of the sea water. The specimens maintained mantles⁶ well extended throughout the test period and customarily "pumped"⁶ for continuous periods of several hours, although continuous flow of sea water in the tray had been used only for a few hours initially. Afterward the sea water in the tray was replaced only twice each 24 hr. The mussels remained alive for many days after the test was discontinued and no further replacement of water made. In another test the water had been taken from the ocean up to 4 days before use and, in general, was replaced only at average intervals of 1.3 days. With this adverse treatment only 2 mussels of the original 46 had died at the end of 12 weeks.

These preliminary tests were made at water temperatures of approximately 50 to 60 F. While this temperature range was favorable to longevity, subsequent tests at summer temperatures gave similar results. Although the preliminary trials showed that batch changes of sea water twice a day were adequate for the usual tests with 1-gal trays,⁷ containing approximately 50 mussels ranging in length from ½ to 1¼ in., flowing sea water was used

⁶ Mantles are fringed membranes between shells through which sea water is received.

⁷ The mussel pumps sea water through his system to obtain food and oxygen.

FIG. 2 LIVE MUSSELS IN TEST TRAY AFTER 6 WEEKS

as preferable for tests at the higher temperatures. It was concluded, therefore, that with simple precautions the common mussel could be maintained indoors in sea water satisfactorily to permit direct comparison of different control treatments.

CONTROL TESTS

Assurance of reasonably comparable results was obtained during the tests of killing treatments by maintaining simultaneously a segregated portion of the mussels of each batch in natural sea water, but otherwise under conditions as nearly similar to those of the test as feasible. Use of such control specimens is a customary procedure in zoological tests.

In the majority of tests no deaths whatever occurred among the untreated specimens. No more than one died from any group of 20 to 50 specimens used for individual tests. The few deaths among control specimens occurred within 1 or 2 days after removal from their natural habitat. No control specimen was lost at any later stage. Hence, the few random deaths of control specimens were not associated with the test manipulation but, rather, were considered the result of earlier natural conditions. The total number lost by deaths under control conditions were so few as to be negligible in comparison with the number killed by the treatment and thus have no significant effect on the conclusions.

PRELIMINARY TESTS OF MUSSEL-CONTROL TREATMENTS

In preliminary tests early in 1947, it was observed that it took more than 6 weeks to kill shelled mussels by continuous chlorination when the sea-water temperature was 50 F, in comparison with about 1 week at 71 F, as reported by Dobson.⁷ This markedly

⁷ "The Control of Fouling Organisms in Fresh- and Salt-Water Circuits," by J. G. Dobson, Trans. ASME, vol. 68, 1946, pp. 247-263.

longer killing time at the lower temperature drew attention abruptly to the great significance of moderate temperature changes in the atmospheric range. As early as June, 1947, a preliminary test indicated that at about 83 F, although complete killing occurred sooner with chlorination than without chlorination, the difference was scarcely noticeable. In another early test at the same period, it was found that at about 93 F, killing was only a matter of a day or two without any chlorine whatever. This led to further investigation of temperature effect.

IMPORTANT EFFECT OF TEMPERATURE OF WATER DURING CHLORINATION

Quantitative results on the effect of temperature of the sea water during chlorination are summarized in Table 1 and presented graphically in Fig. 3, showing the observed effect of various water temperatures on the rate at which shelled mussels are killed by continuous chlorination. The result of a test reported by Dobson⁷ at the single temperature of 71 F, approximately, for partial killing is shown for comparison and correlates satisfactorily. It will be noted that the time required for complete killing at 85 F is only 3 days, whereas at 55 F, the required time is something over 33 days, more than 11 times as great. This brings sharply to attention the very long time required to kill mussels of the Northeast Coast at natural sea-water temperature in winter and early spring.

All results obtained confirm the indication of the preliminary

tests that the temperature of the sea water during chlorination is the most important factor controlling the time required to kill normal shelled mussels. The deviation of results of individual tests from the curves suggests that other variable factors may be present, but subsequent tests to date indicate that they have far less effect than temperature of the water during the killing treatment.

Fig. 4 shows the data of Fig. 3 on "semilogarithmic" plotting paper. A straight-line "curve" appears to represent the data reasonably well. This is convenient because, when making tests under other conditions, a few reliable test points near the ends of

such a curve will establish a satisfactory basis for chlorination control.

During the tests with flowing sea water at the higher temperatures residual chlorine concentrations were maintained at 3 to 0.3 ppm. Hence at temperatures above 88 F the results closely approximate those to be expected in commercial operation. In the tests at lower temperatures the sea water was changed by complete replacement twice a day. The initial concentration of residual chlorine in these was high, but the chlorine was consumed progressively until restored with the next change of water. The average concentration was of the order of 10 to 15 ppm, and more at times. For these tests the resultant killing time probably is too low for the usual commercial concentrations, possibly by 20 per cent.⁸

RESULTS OF KILLING TESTS BY MODERATE HEATING ONLY—WITHOUT CHLORINATION

Preliminary tests had indicated that at temperatures approaching 90 F and higher there was very little difference in time required to kill shelled mussels, whether chlorine was used or not. To study this further a series of tests was conducted without any chlorine whatever. The tests with temperatures of 90 F and above

were made with continuous change of sea water and water-bath equipment.⁹

Obviously, in the absence of chlorine, or other chemical treatment, no killing could be expected at temperatures of 70 F or less, as these temperatures would approach those of natural sea water. However, under the conditions of test, shelled mussels from Lynn Harbor were killed without any chlorine whatever, at a temperature as low as 75 F, by maintaining that temperature continuously for a sufficient length of time. This proved to be more than 12 weeks (test No. 7). Also, observed results confirmed the preliminary conclusions that, at elevated sea-water temperature, chlorination does not reduce the time to kill.

The quantitative results of this series of killing tests without any chlorine or other chemical treatment are summarized in Table 2, presented graphically by the chart, Fig. 5, and plotted on semilogarithmic co-ordinate paper in Fig. 6. In this case a single straight line cannot be applied to the semilogarithmic relation of the data. An abrupt increase in time to kill East Coast mussels is apparent at temperatures slightly less than 85 F.

It will be noted further that above 85 F the time required to kill by continuous heat is approximately the same as when chlorine is used at these temperatures.

⁸ Rough estimate based on tests by Dobson at various concentrations at constant temperature.

COMPARISON OF CHLORINATION, THERMAL TREATMENT, AND COMBINATIONS

Fig. 7 shows direct comparison of killing time, for continuous treatments with and without chlorine, for various water temperatures. Fig. 8 shows the same comparison with semilogarithmic co-ordinates.

From these charts it is obvious that at a temperature of 80 F or less the time required to kill was reduced greatly by chlorination as compared with no chlorination. At 70 F or lower, temperature alone will not give complete killing in any practical operating period, and use of chlorination or other treatment is required.

Conditions at an existing station may determine the most appropriate treatment or may preclude control of fouling by moderate heating alone. In the latter case chemical treatment may be desired. In the case of new construction, a choice may be available in the design stage. Where provisions in construction permit, moderate increase in temperature alone will give positive and complete killing in a predetermined period of 1 to 3 days with no chlorine or other chemical treatment.

If adequate temperature can be maintained at little cost as, for example, during light load periods at a power station, chemical treatment may offer little or no advantage for killing shelled mussels.

TECHNICAL CONCLUSIONS

The most troublesome form of marine fouling observed in stationary conduits was the common mussel.

For complete disposal of marine fouling, it is necessary under usual conditions of commercial operation to kill mussels after their shells are fully developed.

Under all conditions tested, a large proportion of the mussels

Fig. 7 COMPARATIVE TIME FOR KILLING SHELLED MUSSELS—CONTINUOUS TREATMENT

FIG. 8 COMPARATIVE TIME FOR KILLING SHELLED MUSSELS—CONTINUOUS TREATMENT
(Semilogarithmic co-ordinates.)

are killed within a fraction of the time required for killing all. This is significant because, in a power-station circulating-water tunnel, it is desirable, if mussels have accumulated, to remove them gradually so as to prevent clogging by sudden release and accumulation of uncontrolled masses of debris.

The chlorine consumption required to kill shelled mussels can be reduced greatly by increasing the temperature of the water moderately during chlorination.

The time required to kill shelled mussels by chlorination depends primarily upon the temperature of the water in which they are submerged at the time of chlorination. This is a much more significant factor than the variations of the concentration of the residual chlorine within the usual commercial range.

The most significant reduction in chlorine consumption by increasing the temperature of the sea water is obtained at the lower temperatures and for moderate temperature increases.

Complete killing of shelled mussels may be accomplished by the application of moderate increase in temperature alone, with no chlorine or other chemical agent, if applied continuously for sufficient periods.

There are logarithmic relationships between the time required for complete killing and temperature of sea water during killing treatments.

The following conclusions on killing of shelled mussels from Lynn Harbor apply specifically at that location only. They are significant, however, because, generally, similar results may be expected elsewhere, although at different temperature levels:

By increasing temperature of the sea water from 60 F to 70 F, the time required and the chlorine consumption for killing shelled mussels by continuous chlorination are reduced approximately 50 per cent.

With sea-water temperatures raised to 80 F or less, heat alone is quite inefficient for killing shelled mussels, and the use of chlorination or other treatment is indicated.

With sea-water temperatures increased to 85 F, continuous chlorination does not reduce the time for killing below that for continuous temperature without chemical treatment.

When the sea-water temperature is approximately 50 F, the time required for complete killing of shelled mussels by continuous chlorination is about 2 months.

The time required for complete killing of shelled mussels by temperature alone at 90 F was 80 per cent less than with chlorination at 70 F.

CONCLUSIONS ON TECHNIQUE OF SMALL-SCALE TEST PROCEDURE

It was demonstrated that with natural sea water at natural

temperatures, shelled mussels could be maintained in sea water in small receptacles indoors for many weeks in satisfactory condition for comparative tests of killing treatments if reasonable care was exercised in maintaining the natural condition of the sea water by replacing it periodically.

Many useful observations can be made by small-scale tests if the results are considered on a comparative basis, and if a few simple precautions are observed under the guidance of a qualified consultant. This is particularly convenient when it is considered impractical to try changes in the existing method for control of fouling in a commercial power station under heavy demands for power.

Because of the very large variation in the time periods required to kill individual specimen mussels of a given lot under the same treatment, it is important to use a reasonably large number of specimens for a given test in order to determine even approximately the time required to kill all the mussels under a given set of conditions. In general, a minimum of 50 specimens is suggested.

In many tests it was observed that mussels showing the greatest resistance were those of small size, $\frac{1}{2}$ in. long and less; hence these sizes should be included in each batch tested to assure determination of maximum killing time.

It appears desirable to establish a suitable criterion with respect to the varying physical condition of a mussel, or more specifically the resistance to killing. The time required to kill a representative group of 50 specimens by a standard procedure which would approximate a commercial control treatment has been used by the author.

APPLICATION

The small-scale tests have shown that mussels can be exterminated totally on various predetermined schedules of treatment.

The results of the tests are considered adequate for application to routine control of marine fouling of the Northeast Coast if used with liberal factors of safety. Such factors are required in any case because of the considerable variations in the condition of the natural water from time to time and the variations in the condition of the mussels at a given site. If, however, mats of mussels have been allowed to form in the tunnel, or other kinds of fouling must be removed first, it is expected that the time required for killing by continuous chlorination would be increased.

The results of a selected treatment may vary greatly with only moderate changes in conditions. Also, different degrees of control may be desired for different plants because of economic, constructional, or operating conditions. In order to set up a suitable schedule of control treatment at a given plant, therefore, specific quantitative information is desirable. Hence, local tests at the site for each season are recommended.

If for any reason initial treatment in the plant should prove inadequate, it would be necessary only to increase the duration of the treatment or possibly to increase the water temperature gradually, within the limitation of permissible differential temperature stress where massive concrete structures are involved.

The particular type of control for marine fouling to be selected as most appropriate for a given plant would depend on local conditions, including geographical location, fresh-water dilution, if present, industrial pollution, length of tunnel, access, operating conditions, station-load conditions, station design, and the like. This subject, however, is beyond the scope of the present paper.

General results have broad application. Although tests were carried out primarily in connection with the protection of circulating-water systems of power stations, corresponding problems of marine fouling may occur at any coastal plant where natural sea water is used, for example, in salt-water service pipe lines of industrial plants and salt-water fire lines. Salt-water piping systems aboard ships are not immune.

ACKNOWLEDGMENTS

This project has now extended over several years. Throughout we have had the most generous co-operation of a large number of people whose help is gratefully acknowledged. The advice of the following consulting marine biologists was particularly valuable: Dr. William F. Clapp, William F. Clapp Laboratories, Inc.; Dr. Denis L. Fox, Scripps Institution of Oceanography; Dr. Louis W. Hutchins, Woods Hole Oceanographic Institution.

Many power-station operating organizations on both the East and West Coasts have afforded us the advantage of inspection of circulating-water systems when feasible, and full discussion of operating techniques and results. We are particularly grateful to the executives and engineers of the Southern California Edison Company, Long Island Lighting Company, and Lynn Gas and Electric Company. Even from West Africa we received a most painstaking report on practical operating experience with a long submerged tunnel resting on the ocean floor.

The author wishes to express his personal appreciation of the continued interest and help of Mr. William F. Ryan, engineering manager, and Mr. E. B. Powell, consulting engineer, of Stone & Webster Engineering Corporation.

Appendix

TEST PROCEDURE

The general procedure developed in carrying out this series of tests was as follows:

Mussels, as collected from their ocean-shore surroundings, were first retained in trays of natural sea water at moderate room temperature until they functioned in an approximately normal manner before tests were started. The time required to kill the specimens by various treatments was then observed. During the winter, when specimens were taken from their natural habitat at temperatures between 31 F and 45 F, a period of gradual temperature rise of the sea water in the test vessel was allowed before starting the killing test.

For the tests at temperatures of 89 F and above, continuously flowing sea water was used. For other tests it was an essential detail of the technique to renew the sea water in the test receptacles twice daily by emptying and replacing completely so that the water in every part of the test receptacle would be changed.

Mussels for all tests reported were collected at the northeast end of Lynn Harbor on a rocky beach where rubble had been dumped. The harbor extends into an industrial area and has a typical range of tidal elevation of about 10 ft. Size of specimens varied from $\frac{1}{16}$ in. to $1\frac{1}{2}$ in.

Sea water used throughout the tests was taken from the same location in the harbor except on a few occasions when there appeared to be some local contamination. At these times other zones in the same harbor were used.

Sea water used for the control tests was collected from the same source and at the same time as that for the main tests.

Temperature of the sea water in the test receptacles was observed by glass-stem chemical thermometers.

Zonite was used as a convenient source of chlorine.

TEST EQUIPMENT USED

In the tests with water temperatures above 88 F, enameled trays of approximately 1 gal capacity were used with continuously flowing sea water. The arrangement of the equipment used for each test, however, was no more complex than that shown by preceding tests to be necessary. More refinement was required as the water temperature was increased. At approximately 30 deg F above room temperature it was necessary to minimize variations in water temperature during the test, and also to prevent

FIG. 9 DIAGRAM OF TEST EQUIPMENT

nonuniform distribution of temperature across the tray. The equipment adopted is shown in Fig. 9. Uniformity of temperature in the test tray containing the mussels was promoted by the use of a second tray of heated water directly below, acting as a water bath. The temperature of the water bath was controlled by adjusting the elevation of the radiant electric heating elements below the tray. Continuous replacement of the sea water was provided by a small jet supplied from overhead. It was found that the jet of incoming water was sufficient to maintain continual mixing of the water within the tray and thus assure uniform distribution of temperature throughout the test tray. The temperature of the sea water from the jet was raised to approximately that of the water in the test tray by first passing it through a tubular-type electric water heater of special design. The use of a small jet minimized the required capacity of the heater.

Even with a jet approximately 0.02 in. diam, mixing was entirely effective when the static head was only 2 ft, and, with a jet of this small size, it was possible to maintain the siphoning of sea water from the 5-gal bottles overhead for a period of several hours without refilling. No plugging of the small orifice occurred, as the large bottles permitted effective settling of suspended matter in the sea water.

The temperature of the water in the test tray has been shown to be a critical factor, and should be maintained nearly constant for a given test. Since manual adjustments required almost continual corrections at the higher temperatures, an automatic temperature

control is recommended to reduce the attendance and to improve precision.

PROGRESSIVE KILLING

In the earliest tests, it was apparent that the time required to kill shelled mussels by a given procedure varied over a wide range for the individual specimens of a single group in the same test tray and subjected to the same conditions. This is illustrated by the chart in Fig. 10 which shows the rate at which deaths occurred. All subsequent tests confirmed that individual mussels of a given group under test died in succession, suggesting significant differences between the resistance of individual mussels of a group, all of which had lived under the same natural conditions. It was shown, however, that if a considerable number of specimens were used for each test, the time required to kill the entire group gave reasonable correlation of results of various tests. This led to the conclusion that the work should proceed on a statistical basis. Because of the more consistent correlation of the "time to kill all mussels" of the vari-

FIG. 10 RATE OF KILLING SHELLED MUSSELS AT GIVEN TEMPERATURE LEVEL

ous test groups, this measurement afforded a more satisfactory means of showing the fundamentals involved; therefore the time to kill, as reported in Tables 1 and 2, is that required to kill all mussels of the particular group under test by continuous treatment until dead.

Thermal Control of Marine Fouling at Redondo Steam Station of the Southern California Edison Company

By W. L. CHADWICK,¹ F. S. CLARK,² AND D. L. FOX³

The idea of controlling marine fouling by elevating the temperature of the sea water is not new, but it is felt that the application of this means of control in the cooling-water tunnels at the recently constructed Redondo Steam Station of the Southern California Edison Company at Redondo Beach, Calif., contains some features of interest. It is the object of this paper to describe the system employed and to present the results obtained during the first year of operation.

DESIGN CONSIDERATIONS

PRIOR to designing the Redondo Station, it had been observed at the company's Long Beach Station that, whereas heavy fouling growths occurred in the intake tunnels, no serious fouling growths occurred in the discharge tunnels, even though these had never been cleaned in the history of the plant. The only difference in the tunnels to which this freedom from growth could be attributed was the higher temperature of the water in the discharge lines. In designing the Redondo Station, it was decided to utilize this condition to the maximum extent practicable, and also to provide facilities for chlorinating the water in the lines should treatment by higher temperatures not be fully successful.

The Redondo Station is situated on a section of sea coast that is exposed to winter storms and resultant heavy wave action. Hence it was highly desirable to have no structure offshore which would rise above the water and be subjected to pounding by large waves. Also, the beach at the plant site is one of the most popular in Southern California, and consequently no structures could be used that would interfere with the recreational use of the beach by the public.

These considerations precluded the use of a trestle or other structure to support chlorinator lines and a tower at the seaward end to house the chlorine apparatus, but led to the suggestion that two separate submerged lines be constructed out into the sea each of which could be used alternately as an intake or discharge, controlled by flow-reversing gates located on the shore end of the lines.

THERMAL SENSITIVITY OF MARINE FOULING ANIMALS

Biochemical control measures are commonly employed in combating marine fouling. These may involve the application

of toxic paint surfaces to immersed structures such as ships' hulls, or the introduction of chlorine, organic chlorides, or other poisonous solutes into the moving streams of an enclosed system.

However, in an electric power-generating steam plant, utilizing flowing ocean water for cooling its condensers, a rather unique opportunity is offered for an introduction of a biophysical control feature, namely, heat. Two large tunnels at the Redondo plant of the Southern California Edison Company, each 10 ft ID, and extending for nearly 1900 ft into the open sea, are employed as intake and discharge channels, being alternated in these two functions at intervals of 2 to 4 weeks, depending upon the fouling season. Thus the periodic discharge of sea water through each tunnel at elevated temperatures has prevented the growth of fouling animals which have been observed in systems not accorded this treatment.

Experiments at the Scripps Institution of Oceanography reveal the fact that numerous sedentary marine invertebrate animals possess relatively sharp temperature-tolerance thresholds. Sedentary marine algae have not been investigated here, since they fail to colonize dark environments, and hence do not constitute a part of the fouling communities therein. Mussels, barnacles, sponges, tunicates, bryozoa, tube-worms, and anemones constitute the chief sources of trouble. In the Redondo and San Diego areas, the common mussel, *Mytilus edulis*, is the most prevalent member of fouling communities in sea-water tunnels. Barnacles, sponges, and tunicates are secondary foulers, while the large California mussel, *Mytilus californianus*, is an occasional invader at localities employing water from the open sea as distinguished from bays and estuaries which support only the other species, *Mytilus edulis*.

It has been found that the bay mussel, *Mytilus edulis*, is more resistant to exposures in warmed sea water than are *Mytilus californianus*, the barnacles *Balanus tintinnabulum*, *Balanus glandula*, the anemone *Cribrina xanthogrammica*, and other forms. *Mytilus edulis* is exceeded in this respect only by the small ribbed mussel, *Septifer bifurcatus*, but the latter species is so small and relatively sparse in numbers it does not constitute a serious threat.

In order to define working conditions which should hold promise for the practical thermal control of fouling, we therefore selected *Mytilus edulis* as representative of the most populous and relatively resistant fouling organisms common to these waters. Groups of young individuals (about 5-10 mm long, some 3-4 weeks old) were separated carefully and immersed in sea water at closely controlled temperatures for designated lengths of time. At the end of each experimental period, the animals were returned to running sea water and observed for possible survival. Survivors soon part their shells moderately, filter currents of sea water through their siphons, and attach themselves to solid surfaces by spinning the tough threads of adhesive byssus in the normal manner. Thermal casualties part their shells in a gaping fashion, die, and undergo decomposition of the flesh.

The following data have been collected relative to young specimens of *Mytilus edulis*:

¹ Manager, Engineering Department, Southern California Edison Company, Los Angeles, Calif. Mem. ASME.

² Consulting Engineer, Stone & Webster Engineering Corporation, Boston, Mass. Fellow ASME.

³ Professor of Marine Biochemistry, Scripps Institution of Oceanography, of the University of California, La Jolla, Calif.

Contributed by the Power Division and presented at the Spring Meeting, New London, Conn., May 2-4, 1949, and at the Semi-Annual Meeting, San Francisco, Calif., June 27-30, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-8-13.

100	1
95	6-7
90	13
85	41
82	96
77	Survive indefinitely

A graph of the foregoing data yields a smooth exponential curve. It is believed that swimming or freshly settled mussel larvae, being without shells, metabolically active and relatively more sensitive to unfavorable environmental factors, doubtless succumb more readily than do the young individuals which have formed their shells and undergone growth. Thus plant practice, guided by the foregoing data in the Southern California area, provides a generous margin of safety, especially provided that (1) at the height of the marine reproductive season (i.e., from early spring to late fall), water flow is alternated sufficiently frequently (at least every 2 to 4 weeks) to affect the larval or juvenile animals before they have had time to become firmly established, and (2) that temperatures within the upper range are maintained for the periods correspondingly indicated.

Moribund mussels reveal their condition in several observable ways, e.g. (1) by gaping, (2) by failure to close their valves upon mechanical stimulation (tapping the shell), (3) by failure to spin byssus strands for attachment, and (4) by decomposition of their fleshy parts. Even if any or all of the first three diagnostic signs are observable in a treated lot of mussels, it is invariably essential to remove the batch of animals and place them in a container of running sea water at normal temperatures. This was always done in our procedure, by having each lot of ten animals in a large porcelain vessel with perforated bottom (a large Gooch crucible).

At the end of an experimental period, a crucible of experimental animals was removed, drained of water, and the mussels were transferred immediately into a container of fresh cool sea water. This latter container, covered by a screen, was then placed in a running sea-water aquarium, and the experimental animals thereafter were observed during periods of several days. Some heat-narcotized sluggish animals later revive under these conditions, spin byssus, and propel water normally through their valves. On

the other hand, some small mussels which fail to reveal their death by parting their valves, actually may be found to have died in this condition, the shell hinge being insufficiently rigid to operate conspicuously.

Observations always were continued on all animals given heat-treatment for a defined interval and then restored to natural conditions, until such time as we were able to determine that all died as a result of the heat, or that one or more survived. Thus sometimes the data are not all available for 3 or 4 days after the initial thermal treatment. Our data are all plotted on the basis of 100 per cent mortality.

With the use of this method of collecting reliable data, for example, we were able to obtain typical information relative to a series of mussels exposed to a temperature of 35 C or 95 F as shown in Table 1.

The time of 7 hr was manifestly the approximate period to be adopted as the lethal period for mussels of the indicated size and locality, exposed to a temperature of 95 F. Had we merely observed the condition of our animals in the experimental heating vessel, we should have been unable to collect reliable time data for lethality. The believed lethal period thus might exceed the actual lethal period by several or manyfold.

Manifestly the size range of experimental animals, the manner of heating and supplying reviving conditions, and clearly defined criteria of irreversible heat narcosis, leading to certain death, should all be standardized by experimenters in the field.

The definite possibility remains that mussels or other fouling species may vary somewhat in their thresholds of thermal tolerance, according to temperatures prevailing in their normal habitats. Marine animals living on the coast of the Pacific Northwest, for example, might be expected to manifest greater sensitivity, i.e., succumbing at less elevated temperatures and/or within shorter time intervals, than members of the same species, but possibly constituting a separate "physiological race," inhabiting Mexican waters. The sensitivity of races found at intermediate latitudes probably would lie between two such extremes. These matters should be borne in mind, and should be tested experimentally when contemplating the use of flowing sea water from any given region.

DESCRIPTION OF CIRCULATING-WATER SYSTEM

Reference is made to Fig. 1 which shows the facilities for withdrawing water from the Pacific Ocean for the Redondo Station. Two 10-ft-ID precast concrete pipes are laid in the floor of the beach in trenches, having a minimum earth cover of 4 ft, and extend into the sea for a distance of about 1900 ft. The lines were constructed under water by the use of divers, and facilities for unwatering the lines are not provided. The terminal structures are vertical precast concrete towers 14 ft diam, extending about 10 ft above the sea floor and protected by a rock riprap. The top of these towers is about 20 ft below mean lower low water. They are separated laterally by 200 ft to avoid recirculation of the water.

The choice of pipe internal diameter was selected as 10 ft after considering such factors as cost, flow, and possible decrease in diameter by marine growths, with attendant increase in roughness factor. The present pipes will be adequate to handle all the circulating-water requirements for the plant when the latter is expanded to its present ultimate capacity of 264,000 kw. At this load the circulating-water requirement will be about 180,000 gpm.

The shore end of each concrete pipe is connected to a concrete structure in which there are four vertical steel gates which can be raised or lowered with electric motors. The gates are arranged and operated so that one of the concrete pipes acts as an intake and the other as a discharge conduit. At intervals, the position of the gates is changed so that flow is reversed in each conduit. In this way either conduit may be used alternately as a discharge or intake.

Other equipment in the shore structure includes a discharge chamber for warmed water returning from the main condensers in the power plant, a trash rack for collecting and removing seaweed and other trash, revolving screens for removing fish and other marine growth, a suction chamber for the main circulating-water pumps, and a pump house. Circulating water for the main condensers is conveyed from the pumps through 54-in-ID precast concrete pipes laid underground. The latter are not subjected to the antifouling treatment to be described later because it was possible to provide access to them for periodic cleaning by manual means whenever it becomes necessary to do so. Antifouling measures are applied to the two 10-ft-ID pipes under the ocean principally because of their inaccessibility for the usual methods of cleaning.

There is also provided in the pump house equipment for chlorinating the circulating water. Chlorine can be introduced into the water at two places and for two purposes as follows:

1 At the circulating-water pump intake as a desliming agent for the condensers.

2 At the shore end of the 10-ft-ID discharge pipes as a toxic agent for killing marine organisms in the pipe. So far the latter use of chlorine has not been necessary due to the success of the method to be described.

FLOW REVERSAL

The reversal of the circulating water is effected by four vertical gates, one located in each intake and two at the outlets of the transfer basin or reversing chamber. The gates normally will operate in pairs, one intake and one discharge opening, the other pair closing. Gates are 7 ft wide and 10 ft high, built of fabricated steel. They are provided with cast manganese-bronze guides with bronze sealing strips and with stainless-steel stems. The four gates normally operate together at uniform speed, 4 min being required for the complete stroke. The gate hoists are operated electrically, and the position of each is remotely indicated on both the circulating-water panel board in the steam station and the chlorination control panel on the second floor of the chlorination building.

During the 4-min period of reversal there will be a certain amount of recirculation of warmed water, from that gate which has been the discharge and which is now closing, to the intake, which has been closed and which is now opening. The flow in that tunnel, which has been the discharge, is gradually reversing, and some warmed circulating water will be drawn back into the intake. The effect of the reversal of the circulating water is shown in Fig. 2 in which the elevation of the free water level in the forebay has been plotted against elapsed time following the start of the gate movement. This curve sheet is based upon a circulating-water flow of 400 cfs and on a tide level of 0.0. It will be noted that the water level in the intake basin starts at approximately 3 ft below grade 0.0 (which is the head loss in the intake tunnel) and reaches a maximum low grade just after the gates have completed reversal. This lag is a result of the time required to decelerate and reverse the flow of water in the intake tunnel. Approximately 14 min are required for the re-establishment of equilibrium at a level of 3 ft below grade 0.0 (corresponding to the head loss in the discharge tunnel), and a peak water level of approximately 8.5 ft above grade 0.0 is reached just after the completion of the gate movement.

The foregoing maximum and minimum levels are based on an ocean grade of 0.0, corresponding to mean lower low water. When a low tide at -2.5 or a high tide at 7.0 ft occurs, these tide levels below and above grade 0.0 must be superimposed on the level variation shown in Fig. 2. Additional hydraulic data are shown in Table 2.

A weir has been provided at grade 16.0 in the top of the east wall of the transfer basin. Should simultaneous occurrence of

FIG. 2 EFFECT OF REVERSAL OF CIRCULATING WATER

maximum flow, flow reversal, and high tide cause this basin to overflow, the excess water will discharge into the intake basin.

For a short period following tunnel reversal, condensers will receive warmer than normal circulating water owing to the recirculation which occurred when all four gates were open and changing, and to the reversal of the flow in that tunnel which had been the discharge and which became the intake. Fig. 2 indicates that a temperature rise above normal may persist for some 12 min, with a peak rise of 19 deg F prevailing for 3 min. This calculated rise of inlet-water temperature above normal is based upon a heat rejection of 1720×10^6 Btu per hr to the circulating water corresponding to the extreme conditions of four units operating at 66,000 kw. For any lower station load, the magnitude of this temperature rise will be proportionally reduced. It has been found by experience that the reversal cycle does not affect the ability of the main units to carry full load.

ELECTRIC CONTROL OF REVERSING GATES

Each of the four gates is provided with an electric motor operator and means for automatic and manual position control.

Automatic control, under which all four gates operate in synchronism, two opening and two closing, is derived from the chlorination control panel. A manual switch for positioning the four gates synchronously is located on the chlorination panel, while local switches permit the positioning of individual gates. A position indicator for each gate is located on the chlorination control panel and the circulating-water panel in the steam station.

Indicating lights are provided at the chlorine control board and at the motors to show the position of the gates. Red indicates gate fully open. Green indicates gate fully closed. Red and green together indicate gate is either moving or stopped in an intermediate position.

After a gate-positioning operation has been initiated, should an obstruction or a power failure cause any one of the gates to stop before completion of one half of its travel, all gates reverse their travel and are restored to the same position as before operation was initiated. In case the gates have completed more than one half of their travel before one gate stops, all other gates complete the operation. An alarm will sound at the circulating-water gage board if gates go out of synchronism.

BASIS OF PRESENT TREATMENT

The marine fouling organisms which are particularly troublesome at this location are as follows:

- 1 Bay mussel (*Mytilus edulis*).
- 2 Large sea mussel (*Mytilus californianus*).
- 3 Barnacles (*Balanus tintinnabulum* and *Balanus glandula*).
- 4 Hydroids.

Laboratory investigations at the Scripps Institution of Oceanography, University of California, indicated that, of those organisms listed, *Mytilus edulis* is the most prolific and resistant to elevated temperatures, and therefore that any temperature found to be lethal for *Mytilus edulis* would also prove to be fatal for the others. Accordingly, further experimentation to determine the effect of temperature and time of exposure was confined to this mussel as it was abundant and convenient.

The result of the laboratory work is shown in Fig. 3. The curve indicates that this mussel can survive indefinitely at temperatures below 77 F. However, at temperatures above 82 F, survival is dependent upon the time of exposure and, after a temperature of 100 F is reached, the mussel dies within 1 hr.

FIG. 3 RELATION BETWEEN LETHAL TEMPERATURE AND TIME OF EXPOSURE FOR THE MUSSEL, MYTILUS EDULIS

The reproductive cycle of this mussel practically ceases during the winter months when the ocean temperature drops below 60 F, and new mussels do not appear in troublesome numbers until the water temperature increases beyond 60 F in the late spring. Accordingly, it is believed that little or no treatment

will be required during the winter dormant period. Conclusive evidence on this point will not be available until further experience with the system has been obtained.

The information in Fig. 3 is applied to the problem of keeping the pipes free of marine organisms in the following way: During the months when the ocean water exceeds 60 F, the gate positions are reversed periodically, causing a reversal of flow in the two lines so that the line which acted as the intake line becomes the discharge line. As soon as this happens, the temperature of water in the line increases about 19 deg F if full load is being carried in the plant. Depending upon the ocean-water temperature, this is increased further by opening one of the gates partially to cause recirculation of the water to the condenser until the temperature of the water flowing in the discharge pipe is raised to about 102 F. As shown on the curve in Fig. 3, the mussels cannot survive this temperature for longer than 1 hr. To make certain that all mussels and other growths are killed, it has been the practice, during the first summer season that this method has been tried, to maintain this temperature for 4 hours before restoring the gate to normal position and stopping recirculation.

The function of the pipes has been reversed and the temperature of the water increased as just mentioned at varying intervals from 10 days to 3 weeks. It appears that once every 3 weeks may be sufficient and, as later experience with this method develops, it may be possible to increase the length of the interval between flow reversals.

RESULTS

During the summer of 1948 the pipes and terminal structures were treated as outlined, and during this time they remained completely free of any fouling organisms. To check upon the effectiveness of the method, a diver was employed to examine the interior of the pipes and terminal structures at least once a month and oftener during the initial phases of the operation. Also, removable concrete-test panels about 1 ft \times 3 ft were hung in the pipes to provide a spot sample for any growths which might have accumulated. These were removed periodically for examination above water, and likewise were found to be free of troublesome growths throughout the first summer period.

Effectiveness of the method also has been demonstrated in another way. Referring to Fig. 1, in the pump intake chamber there are located, in addition to the main circulator pumps, several small vertical pumps used for station salt-water service.

During the latter part of the first summer's operation, it was necessary to raise these for internal inspection, and it was found at that time that the external surface of the pump columns carried a layer of mussels about 6 to 8 in. thick below the water line. The water surrounding these pumps does not receive the full heat-treatment given to the main conduits, and therefore the mussels are not killed periodically but flourish instead in their unmolested environment. It is reasonable to expect that growths of similar magnitude might have accumulated in the main conduits during the same period had not the treatment described in the foregoing been used.

COST OF TREATMENT

The operating cost of the treatment is relatively small when the benefits derived are evaluated with it. It is also small when compared to the alternative method of using chlorine in lethal quantities to perform the same service. No exact data are available for the latter method because, so far, it has not been necessary to employ the method. However, an estimate has been made of the probable cost of using chlorine rather than heat and is reported here for comparison.

During the 4-hr period when the water temperature is elevated artificially at the expense of condenser vacuum and, consequently, fuel cost, the vacuum drops approximately 1 in. Hg. On an annual basis, it is estimated that the heat-treatment costs about \$800 for the two 66,000-kw turbine generators presently installed. Based upon the best available estimates rather than the actual use of chlorine to accomplish the same results, if such were possible, it is expected that the annual cost of chlorine would be about \$50,000.

While it is true that some additional capital expenditure was necessary to provide the facilities for reversing the flow of water periodically, it is judged that the fixed charges on these are considerably below the annual expense for chlorine as just estimated.

CONCLUSION

A system has been devised for controlling the troublesome growth of marine organisms in two concrete ocean-water conduits by elevating the temperature of the discharge water periodically for short periods to a value slightly in excess of 100 F. The scheme has worked well during the first year of plant operation and has done so at a cost believed to be much lower than with the use of chlorine.

Symposium on Marine Fouling—Discussion

THE following discussion is a composite of that given in connection with the symposium of papers on the subject of Marine Fouling which appears in this issue of the Transactions. References to individual papers of the Symposium will be given by numbers in parentheses as indicated in the following list, which also includes paper numbers.

- 1 "Some Biological Fundamentals of Marine Fouling," by W. F. Clapp, pages 101-107.
- 2 "Project Study for the Mitigation of Marine Fouling," by I. A. Patten, pages 109-115.
- 3 "Control of Marine Fouling in Sea-Water Conduits Including Exploratory Tests on Killing Shelled Mussels," by H. E. White, pages 117-126.
- 4 "Thermal Control of Marine Fouling at Redondo Steam Station of the Southern California Edison Company," by W. L. Chadwick, F. S. Clark, and D. L. Fox, pages 127-131.

DISCUSSION OF PAPERS

HELEN I. BATTLE.¹ The data presented in this symposium offer a definite contribution to the immediate problem of marine fouling and are particularly enlightening to the biologist as an indication of the paucity of specific knowledge regarding the thermal-tolerance ranges of many common organisms.

The possibility of the destruction of larvae prior to or immediately on settling would involve another type of approach to the problem, namely, an accurate determination for any given locality of the following:

- 1 Spawning characteristics of the adult.
- 2 Lethal temperatures and critical temperatures for duration of chlorination of the early larva (*trochophore*), straight hinge (*prodissoconch*) and calcareous shell stage of young (*dissococonch*).
- 3 Preparation of prediction curves for the actual settling time under any given temperature range.

Spawning in *Mytilus* is intermittent and varies considerably in different localities. For example, Fox² found a simultaneous nonperiodic spawning of *Mytilus* at Alexandria and Suez to which temperature apparently had no relationship. Battle,³ for the Fundy area, observed maximum spawning during the summer months at the time of first-quarter neaps, full-moon springs, and third-quarter neap tides, and suggested that spawning might be initiated by increased temperature of the littoral zone when the low water of the first-quarter neaps occurs during the midday. At Wood's Hole, spawning is usual from June to September, at Plymouth, England, from January to May, and in North Wales, in July.⁴ Dr. Clapp (1) has drawn attention to an apparently unusual spawning in December to February, off Portland and Atlantic Beach. Nelson⁵ placed a critical spawning temperature for *Mytilus* at 10-12°C. Miller⁶ found a minimum tempera-

ture of 11-13°C required to initiate spawning at Bideford, P. E. I.

A determination of lethal temperatures and critical temperatures for duration of chlorination of the larval, straight hinge, and young would lend itself readily to laboratory procedure. The eggs either can be fertilized in the laboratory and the young reared successfully on cultured diatoms, or can be obtained in plankton tows with No. 18 bolting silk net. Although it might be expected that the larvae will, in general, be more sensitive to unfavorable environmental factors than the young with shells, this cannot be taken as a generalization, and it would be necessary to determine the thermal death point experimentally.

Dr. J. C. Medcof⁷ has compiled composite curves for the prediction of oyster sets from growth-increment data at various constant temperatures. Such prediction curves would be of the greatest value in the instance of *Mytilus*. Conceivably, in certain localities, *Mytilus* will be subjected to a considerably greater temperature range than that of oysters, hence this will affect the duration of the free-swimming stage and present difficulties in the prediction of the actual settling time.

Further experimental work might be directed along the line of chemical control, possibly by the use of substances to dissolve or destroy the attachment of the byssus thread and not necessarily toxic to the organisms themselves. Such substances, no doubt would bring in the problems of upsetting the balance in nature since the effect might be widespread following their discharge into open water.

C. E. BLAIS.⁸ Paper (4) covering the control of marine fouling by temperature at the Redondo Steam Station is an excellent presentation of the basic treatment successfully carried out on a large-plant scale at this important public-utility station.

The planning, construction, and successful operation of the elevated heat-control method thus established brings into sharp focus the value of this system as compared to some of the other control methods which previously have been suggested and installed for preventing the settling of lava forms and the killing of adult forms of fouling organisms.

The fouling of both fresh and salt-water circulating systems is a common problem to many utility and industrial plants whether they be located on the Atlantic or the Pacific seaboard. The most prevalent source of trouble appears to be caused by those fouling organisms that are members of the *Phylum mollusca*, which includes the snails and other single-shelled *Gastropoda*; and clams, oysters, mussels, and other bivalves that are most troublesome. The *Mytilus edulis* identified as the black mussel on the Atlantic Coast and a similar bivalve that is closely related, known as the *Mytilus californianus*, common on the Pacific Coast, is the most common fouling mollusk throughout the world.

Control methods previously suggested and tried have been numerous, and today, due to the untiring efforts on the part of many eminent biologists and designing and operating engineers, the problem of control can be solved effectively. It is interesting to note that the design of the Redondo Steam Station's marine-fouling-control system was predicated on the two most popular known methods of combating the fouling of salt-water circulating systems: (a) The heating and the recirculating of circulating water, one of the earliest schemes used on a large-plant control

system; (b) chlorination control, probably the most extensively applied of all controlling systems in use today.

The design of the circulatory structure for the Redondo Station is novel and yet not radical. It does, however, contain certain features of much interest to future designers and operators of control installations. Of primary interest is the considered effort to construct, without in any manner interfering with or detracting from the natural recreational area, this necessary facility which otherwise might interfere with the future use of the beach by the public. The engineers are to be commended for the excellence of design, and the ultimate installation which so effectively overcame local difficulties.

The writer concurs with the type of control provided for combating effectively the fouling of the circulating-water lines. The system provides for control by elevated temperatures for primary elimination, and with chlorine injection as a safeguard or for secondary defouling and is worthy of mention. Even though complete and satisfactory results were achieved without the use of chlorine during the first year's run, it is quite within the realm of possibility that this method of prevention might be utilized if future conditions warrant. Experience in the Narragansett Bay area has shown considerable variation in the variety, volume, and the rate of growth of fouling organisms from year to year in any one part of the bay. It is therefore possible that the relatively short period upon which the report is based may not be entirely conclusive as to results.

The operating cost of the treatment for the first year of operation is exceptionally low considering the benefits resulting. A complete breakdown of the cost of the installation of the terminal structure, piping and pumping station would have been quite useful for comparative purposes with other installations, particularly for use in other contemplated studies made for the purpose of determining the specific type of equipment best fitted for the complete elimination of marine fouling in other areas.

The NAS main power plant at Quonset Point was designed and constructed during the duress of the last world war. A pumping station was constructed along the bulkhead south of the main plant, and no control equipment for marine fouling was installed in the initial building unit. The power plant was not long in operation, however, before it became apparent that the infiltration of bay mussels would affect seriously the operation of the turbogenerators. Within the first year of operation, serious clogging of the pump well and large intake and fouling of the condensers necessitated outages at opportune moments to facilitate the defouling of the condenser water boxes, tube sheets, pipes, and pump well. The matter of establishing a satisfactory control was given the highest priority. A survey of the physical features of the cooling-water system indicated that the close and compact arrangement of the prime operating equipment would preclude the possibility of installing the necessary piping for control of marine fouling by temperature. The survey, however, did bring to light the simplicity and feasibility of installing a complete chlorinating system that effectively would control the marine-fouling growth of bay mussels within the system.

An automatic vacuum chlorinator was procured and installed in the pumping station. Chlorine was injected on the lee side of the sluice operating gate before the rotary screen. The chlorinator was placed on automatic control for continuous operation during the warm-weather months, with the chlorine residual maintained at 1 ppm. During the early spring and early fall months up to about October 1, intermittent operation gives satisfactory results. During these periods, the residual is maintained at 0.5 ppm. This system of control treatment has continued to be effective and extremely flexible in meeting the

widely varying conditions, and the operation and maintenance are relatively inexpensive.

LOUIS ELLIOTT.⁹ While a steam plant is not as closely tied to nature as is a hydroelectric, there are still a number of reconciliations to make, of which the supply and handling of condensing water call for one of the most important. This condition obtains whether the station has an ocean, a lake, or a river to draw on for direct condensing, or whether in a dry country cooling towers must be used, with make-up from wells or other source.

The design adopted at the Redondo Station (4), with two 10-ft pipes laid under the sea bottom 1900 ft out from the shore, must presuppose a reasonably stable bottom—not subject to serious change of contour from waves and tides.

The paper (4) brings out the complications arising in a design of this kind—unexpected to one who has not tackled a similar problem. The 10-ft-diam pipes, to carry 400 cfs, give a moderate water velocity, e.g., 5.4 fps. This matter of pipe size was doubtless worked out with care, taking into account investment and fixed charges as against energy losses through friction, and complications arising from variation in head under various phases of operation.

Doubtless, also, the economics as to régime of changes in circulation have been worked out, taking into account necessities of temperature level to kill the mussels, loss of fuel resulting from higher water temperatures, and other elements.

Small-scale examples of similar conditions may be cited. At small steam plants on the Isthmus of Panama, difficulty arises from marine growths inside small pipes taking water from the ocean. These become clogged with mussels and other growths, in spite of the fact that according to Fig. 3 of the paper, the particular mussels encountered at Redondo would have been killed by the temperatures existing in these tropical waters. It is probable that the particular marine growths encountered at Panama are immune to the effect of temperatures that would kill *Mytilus edulis*.

Although no formal research has been conducted, certain approximate results may be compared with conditions in the north (3, 4).

South Avenue steam plant at Panama City has a capability of about 12 mw. There is an unusual condensing-water arrangement, worked out because of the wide shelving beach at the plant site, with the water receding a long distance from the plant at low tide. Circulating water is taken from the sea when the tide is high, and sufficient water is impounded in a basin to supply the cooling needs when the tide recedes beyond the suction line of the pumps. The storage basin is divided into two compartments, permitting certain control of circulation. Some surface cooling is effected during the period when tide is out.

Sea-water temperatures range from 70 F up, and condenser-inlet temperatures from 70 to over 110 F. Fouling by marine growths of pipes and other condensing-water works is experienced, particularly during the spring and early summer. This fouling has been minimized by heating the circulating water for brief periods. Arrangement can be made, daily if necessary, to raise water temperature to 115 F for a period of 20 to 30 min. This has been found effective in killing a great portion of the marine growth.

Data from southern California indicate that exposure of the mussels to 106 F kills them in 20 min. Corresponding data taken at Lynn shows a much longer time for killing all mussels with water at 105 F, and something over an hour with water at 115 F. As just stated, it has been determined at Panama that it is desirable to carry the water up to 115 F for approximately half

⁹ Consulting Mechanical Engineer, Ebasco Services Incorporated, New York, N. Y. Mem. ASME.

an hour. Because of the more general character of information from Panama no close comparison can be made with Redondo and Lynn.

A new plant under design for Panama takes advantage of this utilization of high temperatures, without use of chemicals, for killing marine growth. In this case, as at the South Avenue plant, there is to be a recirculation of warm water, 115 F maximum, through circulating-water conduits and condenser.

The circulating system for the new plant will have a siphon-type conduit 42 in. diam and 500 ft long, supplying water to the intake chamber of the circulating pumps at all stages of tide. This utilization of siphon action, permitting the placing of the intake chamber back on the shore in a protected location, has been made in a number of plants in Central and South America. At the new Panama station, a 12-in. recirculating line from the condenser discharge carries warm water, when required, to the pump-intake chamber and also to the intake siphon. The latter may be valved off, reversing the flow during the periods when high tide floods the intake chamber and the siphon feed is not required. Piping and valves are so arranged that flow can be reversed in each pass of the two-pass condenser, and any part of the circulating system subjected to a higher water temperature to kill mussels or other marine growth.

V. F. ESTCOURT.¹⁰ Although the effect of increased temperature in reducing the ability of mussels to remain attached to intake conduits has been known for many years, the experimental data which have been developed by the authors (4), demonstrating a definite correlation between time of exposure and various water temperatures beyond which specific types of mussels can survive or remain attached, is extremely valuable. This information should prove helpful in designing salt-water condensing systems in power plants for minimum trouble from this type of marine growth. Although the paper (4) relates to what was done to prevent such marine growth in a specific installation, it would appear appropriate to include in this discussion a few observations relative to the basic factors which enter into the problem.

Dr. Clapp (1) adequately describes some valuable research which has been conducted in connection with the chlorination of mussels, and H. E. White (3) correlates the effect of chlorination at different water temperatures in terms of the time required to kill the mussels. None of these papers is concerned with the influence of the basic layout of the salt-water intake system upon the economic application of other methods of control. Therefore some comments regarding this aspect of the problem may be helpful in suggesting a means of evaluating the various possible solutions in terms of how much capital investment can be justified economically for the various methods of control.

The control of marine fouling from the power-plant operator's viewpoint has as its objective the elimination of trouble from restrictions in the flow of cooling water in the various conduits and piping systems, and through the main condensers and other heat exchangers, resulting from the accumulation of mussels, and other fouling organisms at the tube inlets. Four important methods of control have been known for a number of years, i.e., (a) properly located revolving screens, (b) predetermined periodic increments in water velocity, (c) chlorination, (d) predetermined periodic increments in water temperature. Each of these methods is known to be effective in varying degrees, depending upon various local conditions and also upon whether one is used to the exclusion of the other three, or whether some optimum combination of two or more methods is applied. In so far as we are aware, the use of elevated temperatures prior to the Redondo job had

been confined to the process of increasing water velocities periodically, particularly during seasonal high water temperatures; and the effect of chlorination as a means of control had been somewhat inconclusive until the more recent tests at the Lynn Gas and Electric plant were completed (3).

Experience during the past 25 years in the San Francisco Bay area with salt-water cooling systems has indicated that the location of the screens in the intake system is a fundamental factor with respect to operating difficulties which will be encountered from fouling. We have examined intake tunnels up to the location of the revolving screens after many years of continuous operation and find that the accumulation of mussels on the walls of this section of conduit reaches a point of saturation which is determined by the apparent inability of the mussels under existing water velocities and temperatures to maintain a firm hold beyond a certain thickness. Although they may hang down in streamers for a while, eventually they will drop off and are then caught by the revolving screens. It is therefore extremely desirable to locate both the circulating pumps and the screens as close to the condenser as possible. What happens when there are large low-velocity conduits between the screens and the condenser is well illustrated in the paper by I. A. Patten (2).

In most instances there is little to fear from mussel accumulation in the intake conduits up to the point where the revolving screens are located. Absolutely no interruptions or curtailments of operation have resulted from mussel accumulations in this section of the intake tunnel in any of our San Francisco Bay area plants. However, as the authors point out, there were special considerations at Redondo which made it desirable to go to the expense of controlling marine growth in the unusually long intake conduits before the screens. They do not state specifically that smaller conduit cross sections were used in anticipation of an improved roughness factor, and larger effective cross-sectional area due to the absence of mussels. Sometimes other considerations dictate the economic size of the conduit, but it would be of interest to know whether there was any saving in reduced conduit sizes at the Redondo job due to mussel control.

On the other hand, there is a much greater fouling hazard in the section of tunnel or piping between the intake screens and the condensers. It is our understanding that the original design at Redondo for the control of temperature in the intake conduits up to the revolving screens has been extended in its application to the lengths of pipe between the screens and the condensers, in order to meet the problem which usually exists in these sections of conduit which are unprotected by screens. It would be of considerable interest if the authors (4) would describe the results obtained at this point in the system that is, between the circulating pumps and the condensers.

At our Moss Landing steam plant, because there were physical restrictions which made it difficult to bring the revolving screens close enough to the condenser, we not only have manifolded the individual circulating-water-pump discharges, but have arranged the condenser piping so that some or all of the water can be returned in reverse direction through one half of the condenser, thence continuing in reverse direction through one of the pump-discharge lines, thereby elevating the temperature of the cooling water and taking advantage of both increased temperature and velocity, if necessary, in order to remove any mussel accumulations. Had it been economically feasible to locate the revolving screens and pumps within, say, 25 ft or 50 ft of the condensers, these provisions probably would not have been necessary. Full reliance is being placed upon the ability of the revolving screens to prevent any trouble from mussel accumulations in the section of conduit up to this point.

This subject would not be complete without mentioning the

¹⁰ Engineer of Steam Operation, Pacific Gas & Electric Company, San Francisco, Calif. Mem. ASME.

special problem which sometimes develops in small salt-water pipes of, say, 3 in. diam or less. Mussels have been known to grow in these small lines until they are almost completely plugged. This has been eliminated in some instances by the substitution of heavy rubber hose and rubber-lined fittings. Apparently the mussels have difficulty in attaching themselves to rubber, and it would appear that the valuable investigations described in the papers of this Symposium might well be extended to include a further study with respect to the effect upon mussel accumulations of special linings and coatings on the inner surfaces of salt-water conduits.

GUSTAVE HEINEMANN.¹¹ At Corpus Christi plant of the writer's company, large volumes of sea water are used for process-cooling. Although it was planned to commence chlorination of the sea water at the time operations began in 1934, some delays were encountered in the installation of the chlorination equipment. This resulted in our operating the plant for several months with unchlorinated sea water before a chlorination program could be started. Drawing on the experience reported by others, in which it was claimed that shelled mussels could be killed after several days continuous chlorination, it was decided to chlorinate the water on a continuous basis, maintaining chlorine residual roughly 0.5-1.0 ppm for 4 days prior to commencing an intermittent chlorination program. At the end of the 4-day period the lines were flushed, resulting in the recovery of tremendous quantities of killed mussels. Although careful inspection of the lines was not possible, there were definite indications that the kill was essentially complete.

Following the initial continuous treatment, varying programs of intermittent chlorination were tried from 20 min each 8 hr to 40 min each 2 hr. Experimentation indicated that the latter heavier schedule appeared to be necessary for effective control in these waters. With a program of 40-min chlorination each 2 hr, and a residual approximating 0.5-1.5 ppm, essentially complete control is obtained. This experience has also been confirmed by a power plant in this area operating on water from the same source.

It appears evident that in any discussion of mussel control, a consideration of local conditions is of extreme importance. For example, H. E. White (3) shows that with mussels from Lynn Harbor, a complete kill is obtained at temperatures less than 85 F even without the use of any chlorine. W. L. Chadwick, F. S. Clark, and D. L. Fox (4) state that mussels in the Redondo Beach area of California are killed after the temperature of the water reaches 82 F. The growth of the mussels in the Texas Gulf Coast waters is extremely prolific, even during periods when the water temperature is as high as 90 F. This would indicate that the curves which have been presented cannot be applied to normally warm waters such as those in this area.

During the winter season when the water temperature is as low as approximately 60 F, and occasionally as low as 50 F, the rate of mussel growth is decreased tremendously. During the summer season, representing at least 4 or 5 months of the year when the water temperature will be in excess of 80 F, the rate of growth is very rapid. This would indicate that the mussels in this area will withstand temperatures considerably in excess of those at Lynn Harbor or at Redondo Beach.

We do not have any experience to show the effect of temperature on the length of time necessary to kill shelled mussels from waters in this area at varying temperatures using chlorination. Our experience along this line is confined principally to continuous chlorination for 3 to 4-day intervals, such as was employed when

chlorination was first begun, and at times when the water temperatures were in excess of 80 F.

It would appear desirable that further work be instituted to determine the length of time necessary to kill Gulf Coast mussels with chlorine under lower temperature conditions. It also would appear desirable that work be instituted to determine the thermal death temperature of these mussels under varying times of exposure.

B. G. HUME.¹² Marine fouling of circulating-water systems of steam plants on the West Coast has been particularly aggravating to the operating personnel. More trouble has been experienced from marine growth in plants located on open water, where fresh clean sea water is available, than in those located in harbors. Mussels in particular seem to like clean water. Undesirable as it is to have the circulating water contaminated with industrial wastes from a corrosion standpoint; it does discourage the growth of mussels and some other forms of marine life. Mussels are the most objectionable, as they break off from the tunnel walls, and frequently plug the condenser tubes completely or, worse still, lodge inside and cause tube failure from cavitation.

It has been found that chemical control of the circulating water is either too expensive or inadequate to prevent the growth of the more vigorous types of marine life. Therefore it has been necessary to resort to the very expensive method of cleaning tunnels by hand anywhere from one to three times a year. Chemical control still proves to be adequate and quite necessary to prevent the growth of the slimes that are so detrimental to a good heat-transfer rate in condensers, but the mussels protected by shells are highly resistant to chemicals.

The Department of Water and Power of Los Angeles Harbor steam plant uses water from the Los Angeles Harbor. The intake tunnels are about 1200 ft long, and no difficulty has been experienced from marine fouling during the 7 years these tunnels have been in use. In fact, they have been cleaned only once during this time. The sea water in the vicinity of the Seal Beach steam plant, however, is practically free from industrial contamination, hence considerable trouble is experienced with growth of marine life in the intake tunnels.

Mussels grow in great abundance in the inlet tunnels of this latter plant. They hang in festoons on tunnel walls, inlet pipes, and condenser water boxes. As this plant is now being used for hot stand-by service and is generally shut-down over week ends, attempts have been made to discourage the growth of mussels. This was done by injecting chlorine solution into the intake tunnels just before the week-end shutdown, thereby subjecting the growth therein to a "soaking," in water having a residual chlorine content of 2 to 4 ppm.

This procedure has failed to rid the tunnels of mussels, as they apparently close up tightly when the chlorine solution surrounds them and then open up when the danger has passed. Ordinary periodic chlorination for slime control seems to have little or no effect on them.

In designing the extension to the Seal Beach steam plant, the Department proposes to make use of the principles of recirculation in a slightly different manner from those adopted at Redondo. It is proposed that circulating water for the future units at Seal Beach will be taken from Alamitos Bay, as at present, by means of twin 8-ft-diam precast concrete tunnels and discharged to the San Gabriel River. When it is desired to raise the temperature of the water in the tunnels, a portion of the warm circulating water from the condensers will be discharged into one of the intake tunnels. By means of gates, the flow of water will be reversed in this tunnel and warm water will flow toward the

¹¹ Chief Chemist and Technical Director, Southern Alkali Corporation, Corpus Christi, Tex.

¹² Engineer of Steam Design, Department of Water and Power, The City of Los Angeles, Los Angeles, Calif.

intake structure where it will be recirculated and drawn into the other tunnel, and back into the condenser again. It is anticipated this reversal of flow will be done during week ends or other periods of light loads where one tunnel can be spared. In this fashion, the quantity of warm water recirculated can be varied, and the temperature of the water can be controlled to any desired degree. This scheme will permit raising the temperature of the water in the whole circulating-water system sufficiently to kill the marine life, thereby eliminating any parts of the system in which mussels could develop, break away, and get into the condenser tubes, causing tube failure.

The method of preventing growth in tunnels by raising periodically the temperature of the water to 100 F or thereabouts for a few hours, appears to be the answer to a very troublesome problem in this area. Those responsible for initiating and carrying out this very expensive and elaborate experimental work should be highly commended for their part in advancing the art of power-plant design and operation.

L. W. HUTCHINS.¹² The four papers of this Symposium provide a balanced, up-to-date account of most of the aspects of intake-tunnel fouling which are of practical importance, fanging from biological fundamentals to the two cases of plant-scale control.

The very rapid accumulation of fouling in intake tunnels and associated circulating systems is mentioned by several of the authors. Calculations show that the rate of growth in the Lynn tunnel in at least 2 years has exceeded the prodigious figure of 1000 tons per acre of surface per year. No figures remotely comparable are known to biologists from any other sources; thus under the most favorable conditions with the most productive crops, the best farm yields are only of the order of 10 tons per acre per year, for example. From our investigations in the Lynn tunnel, it appears both that the occurrence of large numbers of organisms and the growth of the individuals at unusually rapid rates are factors in the rate of accumulation of that fouling. On the one hand, as many as 6000 mussels have been found on a square foot of wall in the Lynn tunnel. Again, while Dr. Clapp (1) mentions a length of 50 mm being reached after 10 months, a figure which many authorities approximate as normal, in the Lynn tunnel this size may be reached after as little as 17 or 20 weeks.

Most of the common enemies of mussels are excluded from tunnels such as that at Lynn by the trash racks and screens, and probably this is responsible to an important degree for the large numbers of mussels occurring there. Darkness, continuous submergence, reasonably high salinities, adequate oxygen, moderate currents, and sufficient food are all factors which appear to promote mussel growth. It is obvious that an intake tunnel commonly will provide an ideal combination of these, which suggests an explanation of the rapid growth of the individual mussels. An intake tunnel, in short, is probably as close to a perfect environment for mussels as it would be possible to get.

Chlorination has certain effects on mussel growth which perhaps are worth mentioning. Measurements of several thousand mussels from the Lynn tunnel collected at various times over the last 5 years show conclusively that mussels subjected to chlorination are relatively fatter than those growing in unchlorinated water. The concentration of chlorine appears to have no effect in this connection, but the effect becomes more pronounced in mussels subjected to longer treatments in a given period, and it is most extreme in mussels subjected to continuous chlorination. With intermittent treatments of very short bursts, such as the 20 min per 8-hr shift used in 1946, there is no

killing and the over-all growth rate does not appear to be reduced. The result, therefore, due to the slight fattening induced by the chlorination, is to increase the actual bulk of fouling for equivalent numbers of mussels. Chlorination in short treatments thus not only achieves no control, but is actually detrimental in developing a larger bulk of fouling. This seems not to have been known previously.

All of the evidence now available indicates that chlorination, to be an effective control method, must be used in long doses. If intermittent chlorination is desired or necessary, as might be the case in a reversing tunnel system, the schedule apparently should be something on the order of a month on and a month off, rather than a short phase alternation.

Dr. Clapp's demonstration of mussel attachments on test panels at Atlantic Beach in midwinter shows that it is not entirely safe to schedule control methods only for normal fouling seasons. Usually, of course, it is the summer which is the critical time of year for fouling attachment, particularly in the temperate waters where *Mytilus edulis* is involved. Freak off-season sets do occur occasionally, however, and plants should be prepared to employ control methods at any time of year should inspection show that such an unusual set is taking place. It is essential to keep a continuous systematic watch over all installations and not to rely entirely on normal or average data about fouling seasons.

This is especially important in such an installation as the Redondo plant, where the tunnels cannot be cleaned manually and where, therefore, every possible precaution must be taken to maintain them in a clean condition. In this connection it may be noted that while the heavy set of mussels in the Redondo area normally does occur between spring and fall, some mussels are known to breed throughout the year.

Small-scale experiments or laboratory tests are always artificial to some degree and seldom if ever duplicate exactly the conditions obtaining in actual installations or in other tests. Discrepancies are to be expected, therefore, in comparing data from various sources, and it will be noted that there are some in these papers concerning the durations of exposure which are fatal at various temperatures for *Mytilus edulis*.

Thus the data in Mr. White's Fig. 5 (3) do not indicate that the Redondo treatment of 4 hr at 102 F would be adequate, nor do they support Ritchie's earlier use of 12 hr at 90 F at the Edinburgh Westbank Station, although satisfactory control seems to have been obtained at both plants. The differences are minor, however, and do not affect the general concept of control by heat.

Nearly all tests agree in indicating a critical temperature for *Mytilus edulis* in the vicinity of 84 F. Comparatively brief exposures to temperatures higher than this are fatal, while at temperatures below 84 F killing is achieved only by very much longer exposures or not at all. This agrees very closely with what can be inferred from the geographical distribution of *Mytilus edulis*. The southern limit of the species on all coasts throughout the world occurs just about where water temperatures in the hottest part of the summer can be expected to exceed 85 F for several days. Penetration of the species further into the tropics, in other words, would take it into water whose summer temperatures would be lethal. It is possible to make similar inferences about critical temperatures for many other fouling species from their geographical distributions.

Because the economics of fouling control have been debated widely with relatively little evidence, it is valuable to have two further cases in which control has been obtained economically. The Lynn case demonstrates that fouling dominated by *Mytilus edulis*, along with condenser sliming, can be controlled by continuous chlorination at a net saving to the company relative to the cost of maintenance and the less efficient operation without

¹² Marine Biologist, Woods Hole Oceanographic Institution, Woods Hole, Mass.

fouling control. The Redondo case provides a similar demonstration for the high-temperature method, although this is limited to the gross fouling and does not control sliming.

Since there has been considerable doubt of the practicality of fouling control by heat, the Redondo case is also interesting for the very close duplication and confirmation it affords of the experience at the Edinburgh Westbank station reported by Ritchie. Relative costs of chlorination and heat-treatment cannot be determined solely from the Lynn and Redondo data, as given, since neither includes figures for equipment, fixed charges on investment, etc., as well as because only one controls sliming. The Redondo estimates for chlorination there, however, seem high compared to the Lynn costs; solely on the basis of volumes of water handled, the Redondo cost estimate should not exceed about \$15,000 per year at present.

In any event, a final evaluation of the two methods cannot be obtained from only 1 or 2 years' experience at one or two installations; it is to be hoped that further reports on these plants will be forthcoming after the control methods have been in operation several years, and that additional data will be contributed by other units. Meanwhile, all who are concerned with this problem of fouling in circulating-water systems will be indebted to the present authors for their discussions of their experience.

F. L. LAQUE.¹⁴ It is evident that the attention being given the control of fouling in intake tunnels by the authors of papers (3) and (4) is providing a good technical basis for future progress.

At our Marine Test Station at the Ethyl Dow Chemical Company plant, Kure Beach, N. C., we have had opportunity to observe the growth of mussels under conditions which emphasize a point which is indicated also by a comparison of the results obtained in paper (3) as compared with those in paper (4). This point is that the heat that mussels can withstand is likely to be determined to a great extent by what they are accustomed to in their normal environment.

For example, the mussels exposed to the sun between tides on a steel bulkhead at Kure Beach are certainly able to survive combinations of time and temperature which the data of Chadwick, et al, indicate should kill them. Similarly, mussels there have survived the high temperature reached inside the upper surface of a partially buried 3/4-in-thick black steel pipe line which regularly remained full of stagnant sea water during daylight hours when pumps were not operated. Finally, the sea water itself at Kure Beach reaches temperatures during the summer months that may average 83 F with occasional peaks of 86 F. The only effect on the mussels appears to be to stimulate their growth instead of killing them in 80 hours or so, as indicated in Fig. 3 of the Chadwick paper (4).

Perhaps the absolute temperature is not as important as the extent and rate of increase in temperature above normal in determining the killing effect.

All this means, of course, is that the heat-treatment required to kill mussels will have to be established for each location, and results secured at any plant cannot be used as more than a rough guide as to what might be successful elsewhere.

Having in mind, also, the indications in Fig. 10 of Mr. White's paper (3), which show that some mussels are much harder than others, attention might be given the possibility that the offspring of the survivors of a killing treatment in its early stages may become conditioned to it. In time, as the number of survivors increases, it may be necessary to make the killing treatment progressively more severe.

In appraising the results of tests made in the laboratory, due

¹⁴ In Charge, Corrosion Engineering Section, Development and Research Division, The International Nickel Company, Inc., New York, N. Y.

consideration must be given to the possibility that the laboratory environment, in a general way, may be unhealthy. The mussels in the laboratory may, therefore, be more vulnerable to destruction. On this basis, therefore, the data indicating probable life at temperatures approaching normal may reflect largely the ability of the mussels to survive in the laboratory environment. It would be prudent to assume that in practice, killing treatments may need to be more drastic than indicated by laboratory studies.

In reports of the killing effects of chlorination it is necessary to define how the determination of residual chlorine content is made. It has been discovered¹⁵ that with sea water the common ortho-toluidine colorimetric method indicates a chlorine concentration which is about one half that shown by the standard starch-iodide method or by titration with methyl orange. For practical use of results, all that is required is that the method of measuring chlorine be defined or described so that it can be followed by anyone else.

With regard to effects of chlorination on corrosion, some recent tests at Kure Beach have shown that corrosion of 70:30 cupro-nickel alloy is reduced by continuous treatment with chlorine to a residual of 0.5 ppm (ortho-toluidine) and at water velocities up to 10 fps. Intermittent treatment with concentrations up to 3 ppm resulted in a slight increase in corrosion at the highest velocity, with the effect being greater with the longer the interruption of treatment. In general, the observations at Kure Beach, with respect both to killing effects on organisms and possible corrosion of metals, would favor continuous treatment at low chlorine concentrations (0.5 ppm ortho-toluidine) as compared with intermittent treatments at higher concentration.

R. B. MARTIN.¹⁶ During informal discussion following the meeting, particular attention was directed to the exceedingly high (\$50,000) estimate of annual chlorine requirements for the Redondo Steam Station (4) which appeared out of keeping with the chlorine rates and accomplishments discussed by Mr. Patten (2) for the Lynn Gas and Electric Company. The other papers and discussions also gave rise to the suggestion that moderate and economical combinations of chlorine with elevation of water temperatures to accelerate the life processes of the macroorganisms could be counted upon to produce equally good results at a probable saving in heat and in chlorine. Mention was made during the discussions of the continuing experimental work at Kure Beach, N. C., and elsewhere, wherein it is expected that extensive tests can be conducted to prove the value of combinations of low chlorine residuals and moderate elevations of temperatures.

As applied to the Redondo operating conditions, for example, the Lynn methods might call for an annual chlorine consumption for marine fouling of \$6000 for the two condensers now operating, to which might be added \$600 for 26 weeks of normal intermittent chlorination of the 90,000 gpm for slime control; whereas a combination of chlorination with the present use of \$800 of applied heat would use not more than \$70 of chlorine for the 13 annual periods of 4 hr of heating. This combination should show also some promise of alleviating the marine fouling in the pump-suction chamber, and in the discharge piping from the circulating pumps to the condenser-inlet water boxes.

S. T. POWELL.¹⁷ The growth of marine organisms in water-circulating tunnels is a serious problem in the operation of many

¹⁵ "Corrosion of Steel Pipe by Chlorinated Sea Water at Various Velocities," by V. B. Volkening, paper presented at NACE annual meeting, Cincinnati, Ohio, April 14, 1949.

¹⁶ Industrial Division, Wallace & Tiernan Products, Belleville, N. J.

¹⁷ Consulting Chemical Engineer, Baltimore, Md. Fellow ASME.

steam-generating plants using sea water for condenser cooling. This Symposium is most timely and should influence greatly the design of the intake tunnels in stations which are to be built in the future. These problems have been encountered and their importance recognized throughout the world, and it is surprising that control procedures merely by elevation of temperature have not been more universally practiced.

As early as 1903 an attempt was made to control the marine growth in tunnels by the addition of copper sulphate. This treatment was practiced by the Cargo Fleet Iron Company Ltd. of Middlesbrough on the northeast coast of Great Britain. Some beneficial results were obtained from the use of this chemical but the results were not wholly satisfactory. Subsequently, an extensive investigation was undertaken by Dr. James Ritchie of the Royal Scottish Museum in Edinburgh.

The investigation was made to develop a procedure for preventing the growth of mussels in submarine shafts and tunnels at the Westbank Electricity Station at Portobello. The earlier work was supplemented by an investigation to develop operating procedures to prevent blocking of the Portobello tunnels by seaweed. A number of forms of chemical treatment were studied, including the use of chlorine compounds, sulphuric acid, copper sulphate, and other chemicals. Other studies were carried out concurrently to determine the value of temperature variation for the control of mussels and other marine growth adhering to the walls of the tunnels and shafts.

It is most interesting to note the similarity of the findings of the present authors, and those of Dr. Ritchie reported more than twenty years ago. The recommendations made by Dr. Ritchie as a result of his comprehensive study are presented verbatim in the following:

1 "That a reversed current or outflow of heated sea water be passed down each tunnel, and that it be passed until all the water in tunnel and shafts has attained a minimum temperature of 110 F, by which time all the mussels will have been killed.

2 "That it is unnecessary to pass such heated water daily or even weekly, but that to prevent undue development of the mussels in the tunnels the heated current be passed once every four weeks during the spatting season.

3 "That, for all practical purposes, the spatting season and the season during which douching must be continued, may be reckoned from the beginning of March until the end of October.

4 "That immediately after the first application of the above recommendations control observations be made at the grid on the end of the sea-shaft to test the efficacy of the heated overflow."

The principal difference in the findings of the two groups of investigators appears to be the top limit of the temperature requirement for prevention of the growth and development of the marine organisms. However, at the Portobello investigation, it was definitely demonstrated that the temperatures below 100 F were very effective, but the higher temperature was recommended to insure as complete control as possible. It is conceivable, also, that there are different types of organisms encountered at the Portobello Station than those at Redondo and Lynn Harbor.

It would be interesting to evaluate the efficacy of the treatment on the different organisms found at the two stations. It is recognized of course that, as the temperature to which the water heated is increased, the cost of the treatment increases, and it is obvious from the standpoint of economy that the temperature should be raised only to the point at which the efficacy of the treatment is commensurate with the increased operating cost.

The writer was interested to note that the authors of these papers have drawn attention to the fact that this form of treat-

ment is not a substitute for control of bacterial slimes forming on condenser tubes, but the thermal treatment is a specific corrective measure for the control of shelled mussel growth. It would be interesting to evaluate the increased rate of growth of bacterial slimes resulting from the occasional increase in the temperature of the water. It is possible that the growth of bacteria responsible for slimes might increase because of the more favorable temperature of the water during the life cycle of the organisms. Other factors may be encountered because of the changing biology of organisms present in the water resulting from the elimination of the mussels.

LESTER RANDALL¹⁸ AND D. DOUGLASS.¹⁹ Favorable results in the control of marine fouling by intermittent chlorination at the steam station of Stamford Gas & Electric Company were obtained January, 1942, to August, 1945. The tests relate to a 25,000-kw installation which started operation in 1942. The circulating-water pipes carrying the sea water from the pumps at the screen well are 3 ft diam and have a total length of 262 ft. The load conditions have been such that the reported velocity of 5 fps has been maintained almost continuously. The present schedule of chlorination consists of feeding 60 min per 24 hr and maintaining a residual chlorine concentration of approximately 0.5 ppm at the condenser discharge.

The amounts of marine fouling removed annually from the circulating-water pipes were as follows:

Year	Marine fouling removed, cu ft
1945.....	3.7
1946.....	11.2
1947.....	12.5
1948.....	6.0

Continued accumulation of marine fouling at rates in excess of 200 cubic feet per year in the pits where chlorine had not yet dispersed, indicates corresponding accumulations would have continued in the pipes if chlorination had not been applied. The accompanying charts, Figs. 1 and 2 on the following page, show typical water temperatures in the intake, but it should be noted that these are in excess of natural sea-water temperatures for the locality because of partial recirculation of the heated circulating water.

G. K. SAURWEIN.²⁰ The Cannon Street Station of the New Bedford Gas and Edison Light Company is located on tide water at the mouth of the Acushnet River on Buzzards Bay. It was built by Stone & Webster in 1916. Several extensions have been added through the years and now the station has the following installed capacity:

- 1 10,000-kw unit at 210 psi, 500 F temperature
- 2 15,000-kw units at 210 psi, 500 F temperature
- 2 20,000-kw units at 210 psi, 500 F temperature
- 1 25,000-kw units at 875 psi, 900 F temperature
- 1 7500-kw topping unit at 875 psi and 850 F temperature

There is currently being installed a 30,000-kw 900-psi unit.

The units now in service require about 90,000 gpm supplied through a traveling screen house and an 11-ft-wide 6-ft-high intake tunnel running the length of the powerhouse, about 450 ft, with several suction wells each about 10 ft × 18 ft. This tunnel had no gate or other means for stopping off the water, and has never been cleaned.

About 20 years ago shell material began to get into the con-

denser water boxes requiring shutdowns for cleaning. Shell trouble varied greatly from year to year; some seasons quantities were very large, and in others almost negligible. This trouble was not very disturbing during the 1930's when there was plenty of spare capacity in the station. However, when war activity began and load increased, these interruptions were serious. In 1939 R. D. Stauffer, chief engineer of the system, conceived the idea of providing a large-size blowdown connection at the bottom of the inlet water boxes. Twenty-inch "blow-down" connections were installed on the 20,000-kw units and 16 in. on the 15,000-kw units. These cut the time of cleaning water boxes from $1\frac{1}{2}$ hr to 7 min. This of course did not remedy the tunnel condition. More shell material was continually accumulating and obstructing the flow of water. Examination by diver in 1943 showed that the sides and roof were encrusted with matted seaweed and mussel shells to a depth of 6 in., and the accumulation of material on the floor varied from 1 ft to as much as 3 ft in depth. The discharge tunnel contains none of this material.

Due to the summer population of Cape Cod, the peak load on this plant occurs during the summer months, when the water is warm, use of condensing water greatest, and activity of the mussels at a maximum. To stop condenser plugging, it is imperative that the tunnel be cleaned. Therefore it was planned to install a gate in the tunnel, and to provide auxiliary condensing-water supply to the three largest units in the plant which will carry week-end loads. The tunnel may then be shut down over one or more week ends for the cleaning operation.

Three 15,000-gpm vertical pumps have been installed and connected by concrete and cast-iron piping to the 25,000-kw and the two 20,000-kw units. These pumps are so arranged that two may serve the new 30,000-kw unit now being installed, leaving one spare pump.

An 8-in. vertical dredge pump has been provided for handling the solid material. It will be lowered into the tunnel at convenient points along its length. When the auxiliary condensing-water pumps are in service, the tunnel gate will be closed and the tunnel pumped down to a 2-ft depth of water which will be maintained for flowage of the solids to the dredge pump.

A crew will then enter the tunnel with spades, scrapers, and rakes to move the solid material to the dredge pump. The pump will discharge through a pipe line laid with dresser couplings to a collection point at the dock. About 500 cu yd of material will have to be removed from the tunnel and the pump suction pockets.

The first chlorinating equipment was installed in the plant in 1937, when a 720-lb per day unit was put in. In 1940 this was replaced by two 2000-lb per day units. This equipment controls slime well but could not remedy the mussel condition. On October 3, 1943, officials of the company met at the plant with representatives of the Wm. F. Clapp Laboratories to examine the tunnel and discuss remedies. It was suggested then that higher rates of chlorination be used to give up to 3 ppm residual at the condenser tail pipes. However, larger chlorinating equipment has not been installed to date. A plan is now being considered of light intermittent dosing of about $3\frac{1}{2}$ ppm for slime control and a heavier continuous application during the summer months for mussel control. According to the Lynn experience, continuous chlorination during the summer with a residual of only 0.25 to 0.50 ppm will be effective. After removing the accumulation of solids from the tunnel it will be possible to keep it clean.

Cost of, auxiliary condensing-water installation and tunnel-cleaning equipment will approach \$100,000. Cleaning operations will be reported when completed.

CLOSURE TO PAPER (3) BY H. E. WHITE

The wide recognition of the importance of this project is evidenced by the breadth of discussion, which has significantly en-

hanced the value of the original papers. The specific appreciation of the background work expressed by Mr. Hume is particularly gratifying.

Dr. Battle's interesting discussion includes an outline of a rational procedure for studying the killing of mussels while very young, immediately upon arrival in an intake tunnel. Presumably, this would lead to continuous treatments at times determined by the active spawning periods. Certain of the proposals advanced might also bring improvement in existing methods of control:

- 1 Killing treatments for embryonic mussels can be successfully studied in the laboratory.

- 2 Spawning periods, although at some sites independent of water temperature, might be predictable with the aid of supplementary factors.

In case predictions were inaccurate, or unintended interruptions of the proposed treatments occurred, shelled mussels might develop and make necessary a return to types of treatment suitable for the adult form.

The possibility of destroying the mussels' attachment threads would make an interesting study, although preliminary trials were not encouraging for commercial application. The material resists long exposures to free chlorine approximating 100 ppm.

We are indebted to Mr. Elliott for extending the geographical range of observations to Panama where marine fouling organisms live at a minimum sea water temperature of 70 F, and 115 F is required for 30 minutes to give commercially acceptable control. It is striking that, where impounding basins may give temperatures of intake water exceeding 100 F during normal operation, the killing temperature may be only about 15 F higher.

Mr. Escourt's report further extends the range of data to San Francisco Bay. In that area, apparently, detached mussels are swept along the floor of the tunnel by the flowing water to the traveling screen and are there carried upward for disposal. Although somewhat similar action does occur on the East Coast with the lesser masses of small mussels, the typical thick mat in a zone ineffectively treated may merely fall to the floor and remain as a stationary obstruction. An accumulation from 1 ft to 3 ft deep of fouling debris in the tunnel at New Bedford was reported by Mr. Sauerwein. Greater depths have occurred elsewhere. Apparently, the volume of fouling carried along the tunnel to be lifted by a traveling screen would depend upon the effective water velocity and the size and effective specific gravity of the individual masses after detachment.

With reference to the use of rubber lining as a means of discouraging attachment of mussels, this might receive more detailed observation to determine the period for which the rubber surface would remain an effective retardant.

Mr. Heinemann reports that the typical winter temperature of the water at Corpus Christi is 60 F with continuing summer temperatures in excess of 80 F and that, in other Gulf Coast areas, growth of mussels is extremely prolific with natural water temperatures of 90 F. As these higher temperatures would kill mussels in the vicinity of Massachusetts in a few days, these Gulf Coast mussels obviously require higher temperatures for killing than those on the East Coast as he points out. It is also interesting that approximately complete killing is accomplished at Corpus Christi by continuous chlorination within four days at 80 F, suggesting that the resistance of mussels on the Gulf Coast to chlorination may not differ greatly from that of the mussels along the northern coast. The further studies which Mr. Heinemann suggests should add to the understanding of fouling control.

Mr. Hume's observations at Seal Beach Station on the ineffectiveness for mussel control of "soaking" chlorination over a week

end and the usual intermittent chlorination for slime control are in general accord with the test curves for chlorination. For accomplishing control within week-end intervals, killing may be accelerated by temperature rise.

Dr. Hutchins concludes that short, intermittent periods of chlorination are ineffective for killing shelled mussels and that longer periods of several weeks each would be much more efficient. This thesis is thoroughly supported by observations at Lynn, but variant cases reported in the symposium include stations at Stamford, Connecticut, and at Corpus Christi, Texas, although the partial recirculation may be a factor at Stamford.

Mr. LaQue's conclusion that conditions in tunnels of power stations may differ from those in small-scale tests is substantiated by specific observations. For example, mussels may have been permitted to gather into a continuous thick mat on the walls of the tunnel before the killing treatment is applied. This diverts the main current of water and may greatly extend the time required for the treatment to take effect on the organisms closest to the surface of the wall. In this case, the treatment required in the tunnel may be considerably longer than a laboratory test on individual mussels would indicate. Notwithstanding, it may be noted that the small-scale tests are generally applicable to the treatment actually reaching the individual mussel of a mat.

Another factor which may be important is the time of travel of the water through the tunnels. For a long tunnel this might be a half hour or more at light load. During such a period, the free chlorine initially available for killing at the point of introduction might be largely consumed by the accumulated organisms on the walls before reaching the farther end of the tunnel. Again, it may be noted that the small-scale tests indicate the concentration of chlorine which must actually reach the individual mussel in the commercial installation.

Mr. LaQue suggests that the second generation of mussels may have much more resistance to a given temperature treatment than the predecessors. This is probably so. Apparently, however, it is unnecessary to wait for a second generation, as limited observations indicate resistance of a given group of mussels to a given heat-treatment may increase within a few weeks.

Mr. Martin's suggestion as to possibilities of moderate temperature increase to minimize chlorine consumption may find application where moderate recirculation is already available, as for ice control.

Mr. Powell refers to the commendable pioneering work of Dr. James Ritchie. Dr. Ritchie showed that fouling could be controlled by heating without use of chlorine. As suggested by Mr. Powell and as clearly demonstrated by the present symposium, there is a wide variation in the required duration of a given killing treatment at different sites. It was, therefore, necessary to make specific tests at Lynn and Redondo to approximate reliable control schedules. The present paper includes, in addition, charts of specific effects of temperature on chlorination and approximate comparison of chlorination with control by temperature alone.

Messrs. Randall and Douglass report continued satisfactory commercial control of marine fouling at the steam station of Stamford Gas and Electric Company while using intermittent chlorination 60 minutes per 24 hours with a residual chlorine concentration of approximately 0.5 ppm at the condenser discharge. Possibly, the temperature rise from partial recirculation outside this station simulates to a degree the results at Panama where controlled external recirculation gives effective control by temperature alone.

Mr. Sauerwein's discussion illustrates limitations which develop where peak loads occur when growth of marine fouling is at a maximum. Possibly a contributing cause of the previous ineffectiveness of chlorination at Cannon Street station was an

insufficient period of treatment, particularly at the base of the thick mass of accumulated mussels.

Economics

Messrs. Blais, Elliott, Estcourt, Hume, Hutchins, Martin and Powell raise questions concerning the relative economic value of chlorination as compared with temperature rise alone or combinations. This was mentioned only briefly in the paper. Economic selection of treatment might be based logically on conditions at each individual station; particularly on (a) the steam consumption characteristics of the main turbine units, (b) the expected electrical load conditions, (c) the feasibility of reversing the flow of circulating water, and (d) the resistance of the local fouling organisms.

Where the temperature rise for control of marine fouling is obtained by partial recirculation of the circulating water, a reduction in vacuum on the main turbine generally occurs. For stations designed for stand-by service, the temperature rise of the circulating water through the condenser may reach approximately 20 F with no recirculation. Under these conditions the additional rise required for the desired killing treatment may be moderate. Many turbine generators recently installed are of the "preferred standard" type. As is well known, the effect of reduced vacuum on steam flow to the throttle for this type of turbine may be almost negligible at the high loads. In other words, for this particular design of turbine, under prevalent electrical loads water may be heated with very little increase in station fuel rate. For turbines of other designs and other loads, however, the costs might be considerably higher.

Where killing is desired within the minimum time from the beginning of treatment, as during a holiday shutdown, minimum elapsed time would be expected if treatment were continued until final death, as in the tests of the present paper. Where the cost of heating water is low, this may be a convenient practice. On the other hand, where heating cost is significant and time is available between treatment and delayed death, the cost of treatment may be significantly reduced, under some conditions at least, merely by reducing the duration of the treatment, as brought out by Dr. Fox.

Test Procedure

Dr. Hutchins and others were interested in details of test procedure used, particularly for possible comparison of reported results with those obtained by other procedures at widely separate sites. For reasons of space limitations, much detail was omitted from the original paper. The following amplifying comments may be helpful in interpreting the test procedure.

At the outset of the project the results of Dobson's²¹ test were the most specific published data found for mussels in the New England area. At least approximately comparable results seemed desirable. Fundamentally Dobson's procedure was adapted to indoor manipulation by the equipment described in the present paper. The principal deviation from Dobson's procedure was that the tests were continued until all specimens were considered dead. The reason for this was the considerable increment in the length of treatment required to kill the last survivors.

Specimens were retained in the trays under treatment until all were "dead." The criterion used to determine the time of death was the time when specimens no longer responded to a sharp needle applied to the soft tissues between the reopened shells.

When the killing treatment was discontinued before elapse of a substantial portion of the time required for final death of all mussels in the test tray, the following results were observed under New England conditions:

- 1 A few mussels had already reached final death.

²¹ The Control of Fouling Organisms in Fresh- and Salt-Water Circuits, by J. G. Dobson, Trans. ASME, vol. 68, 1946, pp. 247-265.

2 Some mussels which survived the treatment period died subsequently, even in sea water at atmospheric temperatures.

3 Other mussels which survived the treatment did not die subsequently when returned to sea water at atmospheric temperatures but instead recovered to various degrees.

Item 1 is as expected from the principle of progressive killing described in the paper. Item 2 is illustrated by data by Dr. Fox in the paper published on pages 127-132 of this issue. With respect to item 3, various degrees of recovery were evidenced by: voluntary closing of shells after water was poured from the test tray, voluntary opening of shells when water was replaced, voluntary extension of the mantle from between the shells and retraction, extension and retraction of the foot, movement of the mussel along the floor of the tray, climbing of side wall of tray, secretion and attachment of new byssus threads.

Recovery was very gradual, in some cases occupying weeks. Under such circumstances positive determination of the final condition of the specimens would have consumed much more time and attendance than was available. Therefore, to meet urgent engineering requirements, all treatments of the tests presented in the paper were continued until final death of all mussels in the test tray, to assure positive killing. The numerical values are specific only for the location, times, and treatment stated. Local tests are recommended for each individual site.

Several sources of uncertainty were observed to arise in a small percentage of cases under the procedure adopted. One possible source of error was the deferred opening of the shells after death had occurred. This delay was detected, in some cases at least, by flotation of the specimen. In cases where the shells were attached close to the bottom of the test pan, flotation was shown by carefully cutting the retaining threads. Delay in the opening of the shells was also indicated at times by the release of minute gas bubbles from between the shells of an individual mussel. Other possible sources of error were observed, but formal discussion would require more specific and detailed observation over a wide range of conditions. Where time of death was uncertain, specimens were eliminated from the tests. Since practical application of the small-scale tests would require observation of a given treatment under actual conditions of commercial operation and subsequent readjustment, the results were considered adequate for the purpose of the exploratory tests if applied with reasonable factors of safety.

While the immediate engineering objectives have been met, it is hoped that others will have opportunity to develop refinements which will lead to more precise control through more detailed observation. Data by Dr. Fox is a valuable contribution in this direction, as illustrating specifically the possible reduction in the duration of a treatment in the upper temperature range by taking advantage of delayed death. It is hoped that others may study the possibility of similar reduction in the lower temperature range, appropriate to chlorination.

It would appear necessary to have available more observational data on the reaction of the organisms under the various conditions of habitat and at various temperature levels before making direct comparison of results obtained at different sites by different procedures.

We concur with Dr. Hutchins that there would be great value in extending the observations of killing treatments at many more sites to show the maximum range of the reaction of the mussels in various geographical locations for different years and seasons. A rather simple test procedure might encourage wider participation by regular operating personnel of industrial plants.

Comparison of results obtained at different sites would be facilitated if test procedures could be standardized as originally proposed. In this Dr. Fox concurs. For the present, possibly two types of procedures might be set up:

1 A test, for adoption where opportunities permit, for more precise observation at a given site by a suitably equipped biologist.

2 A simpler procedure which might find wider use by personnel of industrial plants.

In any case, it would seem appropriate to examine further the procedure for determination of residual chlorine as proposed by Mr. LaQue.

CLOSURE TO PAPER (4) BY W. L. CHADWICK, F. S. CLARK,
AND D. L. FOX

The authors are grateful for the interesting and valuable comments contributed in the several discussions of their paper.

Mr. Elliot and Mr. Estcourt have asked about selection of pipe diameter for the sea lines. Several factors influenced the choice of diameter, the principal ones being cost and availability. The first units at Redondo Steam Station were constructed under an extremely close time schedule and many items were selected because of early delivery. In the early stages of design, consideration was given to the use of 9-ft-diam pipe, which would have given reasonable maximum velocities and friction losses, even allowing for a considerable accumulation of marine growth and debris. Flow calculations were based on Williams' and Hazen's formula for friction coefficients of 120 initially and of 90 for extreme allowable fouling. However, when contract bids were available and, hence, when construction costs and deliveries could be considered, it was found that one bidder had forms and equipment for handling 10-ft-diam pipe already available, and that the 10-ft-diam pipe was offered with earlier delivery at practically the same installed cost as the 9-ft-diam pipe. Accordingly, the choice was made on this basis.

Mr. Estcourt also inquired as to the effect of temperature control on the portion of the circulating-water system between the screens and the condenser. During the 1949 season, elevated temperatures have been employed throughout the entire salt-water circuit with beneficial results. The fouling has been greatly reduced in the condensers and in the lines between the condensers and the gates. Furthermore, a marked reduction in the amount of slime adhering to the condenser tubes has been noticed during this period. At this time (November, 1949), chlorine has not been used for 16 months, either for mussel or slime control.

Dr. Hutchins and Mr. Martin have questioned the estimated annual cost of chlorination. The estimate may seem high, but it was based on the rate of chlorination which experience in this area has indicated would be necessary to obtain satisfactory control of the severe fouling which would be expected at Redondo.

The authors would like to emphasize that at Redondo Steam Station provision for elevated-temperature control of the fouling did not involve a significant increase in cost. Since along the exposed coast at the plant site an accessible intake structure was not feasible, full provision for reversal of flow was necessary in order to provide for chlorination from the shore, hence only a small additional capital expenditure was required in order to permit raising the temperature of the discharge.

The authors are indebted to Mr. T. M. Hotchkiss for his able assistance in the preparation and presentation of the paper.

Mr. Blair mentions *Mytilus californianus* as the most common fouling mollusk on the Pacific Coast. In this connection it should be pointed out that *Mytilus edulis* likewise occurs on the Pacific Coast in vast numbers, and that it is, in fact, more tolerant toward both heterosmotic and thermal extremes than is *Mytilus californianus*. *Mytilus edulis* constitutes by far the most prominent fouling organism in sea-water conduits on the Southern California coast.

The point raised by Messrs. Elliott, Heinemann, LaQue, and Powell, regarding the relative thermal resistance of fouling organ-

isms as correlated with temperatures prevailing in their natural habitat, is very well made. This is indeed a recognized fact which applies to physiological races of the same species. *Mytilus edulis*, being a widely distributed form, is an outstanding example of thermal adaptability. This matter should always be kept in mind if construction of new sea-water tunnels is to be undertaken at contrasting latitudes.

Concerning the temperature and time thresholds for killing mussels at Lynn, it will be of great interest to learn exactly what kind of observational data were collected for the recognition of death or approaching death. A mussel which has received lethal

thermal treatment may not necessarily die on the same day¹ but may expire a day or two later, even after cool flowing sea-water has been restored.

Failure to spin new byssus threads, persistent gaping of the valves, even after mechanical stimulus, or "sulking" (i.e., remaining with valves continuously closed) for long periods, after the return from a warm environment to water of normal temperatures, are recognized signs of moribundity. Needless to say, such signs are of paramount importance if one is to make accurate determinations of the critical temperature and time required for lethality.

Forming of a Plastic Sheet Between Fixed Cylindrical Guides With Coulomb Friction¹

By H. I. ANSOFF,² SANTA MONICA, CALIF.

The purpose of this investigation was to obtain a rigorous analysis of the drawing of a plastic sheet between two fixed cylindrical surfaces. A number of solutions have recently been given (1, 2, 3, 4, 5)³ in which the following fundamental assumptions are used: (a) The material between the cylinders is in a state of plane plastic flow and behaves according to the Saint Venant-Mises theory; (b) the normal stress in the direction of drawing σ_x and the normal stress at the boundary σ_y are the principal stresses, (c) the horizontal stress σ_x is constant over each cross section. In the present treatment only assumption (a) is retained. Shevchenko (4) has recently solved this problem assuming that the shearing stress at the walls is proportional to the relative velocity between the wall and the plastic material.

STRESS DISTRIBUTION IN PLANE PLASTIC FLOW

CONSIDER the plane flow of a plastic material in the x, y -plane and let σ_x, σ_y , and σ_z be the normal stresses in the x, y , and z -directions, respectively, and $\tau_{xy}, \tau_{yz}, \tau_{zx}$ the shearing stresses. For plane plastic flow

$$\tau_{xx} = \tau_{yy} = 0 \text{ and } \sigma_z = \frac{1}{2}(\sigma_x + \sigma_y)$$

Thus the state of stress can be described completely in terms of σ_x, σ_y , and τ_{xy} ; the latter stress component, for convenience, will be denoted by τ .

The dependence of the stress components on the orientation of the co-ordinate axes is easily described by means of Mohr's circle. Consider an arbitrary point P in the stressed medium and let a surface element through P and perpendicular to the x, y -plane be rotated continuously about the parallel to the z -axis through P , Fig. 1. Further, let α denote the counterclockwise angle between the element and the negative y -axis and σ_α and τ_α the stresses transmitted from the unshaded to the shaded side of the element. Thus, for example, $\sigma_0 = \sigma_x, \tau_0 = -\tau$ and $\sigma_{\pi/2} = \sigma_y, \tau_{\pi/2} = \tau$ as shown in Fig. 1. Now, for any given position of the surface element, the stresses transmitted across it are represented by the co-ordinates of a point on the circumference of a circle with center $[(\sigma_x + \sigma_y)/2, 0]$ and the radius equal to the maximum shearing stress

¹ The conclusions presented in this paper were obtained in the course of research conducted under Contract N7onr-358 sponsored jointly by the Office of Naval Research and the Bureau of Ships. The paper forms the first part of a thesis submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Applied Mathematics at Brown University, Providence, R. I., August, 1948.

$$\tau_{\max} = \sqrt{\frac{1}{4}(\sigma_x - \sigma_y)^2 + \tau^2}$$

Fig. 2 shows this circle and, in particular, the points representing the stresses transmitted across the various surface elements shown in Fig. 1. It should be noted that the angle between any two points on the circumference is twice the angle between the corresponding elements of Fig. 1.

FIG. 1 STRESS DISTRIBUTION IN A PLANE

FIG. 2 MOHR'S CIRCLE

The following terminology will be used in the subsequent discussion. At two definite angles $\alpha = \alpha_1$ and $\alpha = \alpha_{11} = \alpha_1 + \pi/2$ the normal stress becomes maximum and minimum, respectively, and the shearing stress vanishes. The directions defined by α_1 and α_{11} , Fig. 1, are called the "first" and "second principal directions," respectively. The shearing stress becomes maximum for the angles $\alpha = \theta_1 = \alpha_1 + \pi/4$ and $\alpha = \theta_{11} = \alpha_{11} + \pi/4$. The corresponding directions are called the "first" and "second shear directions," respectively. Thus the first shear direction is along the bisector of the counterclockwise angle between the first and the second principal directions. In the following it will be convenient to omit the subscripts and to designate the angle between the negative y -axis and the first shear direction by θ .

The curves in the x, y -plane which are everywhere tangent to the first shear direction form the "first family of shear lines." The "second family of shear lines" is similarly defined as the

family of curves which is everywhere tangent to the second shear direction. Shear lines of different families intersect each other at right angles.

BASIC EQUATIONS

The discussion in the preceding section applies generally to the state of stress under conditions of plane strain. If the stressed material is elastic, then the radius of Mohr's circle varies with the position of the point P . If, on the other hand, the material is in the plastic state, then, according to the Saint Venant-Mises theory, the maximum shearing stress has a constant value k throughout the plastic region. Accordingly, Mohr's circle has the same radius k for any point P in the plastic region and the stresses in the plastic region are then related by

$$(\sigma_x - \sigma_y)^2 + 4\tau^2 = 4k^2 \quad [1]$$

If body and inertia forces are neglected, the equilibrium equations take the form

$$\left. \begin{aligned} \frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau}{\partial y} &= 0 \\ \frac{\partial \sigma_y}{\partial y} + \frac{\partial \tau}{\partial x} &= 0 \end{aligned} \right\} \quad [2]$$

Under appropriate boundary conditions, Equations [1] and [2] completely determine the state of stress in the medium without reference to the stress-strain laws. The problem then is statically determinate.

With

$$\omega = (\sigma_x + \sigma_y)/4k \quad [3]$$

the stresses may be written in the following form, see Fig. 2

$$\left. \begin{aligned} \sigma_x/k &= 2\omega + \sin 2\theta \\ \sigma_y/k &= 2\omega - \sin 2\theta \\ \tau/k &= -\cos 2\theta \end{aligned} \right\} \quad [4]$$

In Equations [4], ω is one half of the mean normal stress divided by the yield stress in pure shear k , and θ is the angle between the negative y -axis and the first shear direction.

Substitution of Equations [4] into [1] yields an identity, and substitution into Equations [2] yields

$$\left. \begin{aligned} \omega_x + \theta_x \cos 2\theta + \theta_y \sin 2\theta &= 0 \\ \omega_y + \theta_x \sin 2\theta - \theta_y \cos 2\theta &= 0 \end{aligned} \right\} \quad [5]$$

where the subscripts x and y indicate differentiation with respect to these variables.

Let

$$\xi = \omega + \theta, \quad \eta = \omega - \theta \quad [6]$$

Substitution of Equations [6] into Equations [5], yields the canonic form of the partial differential equations of plane plastic flow (7)

$$\eta_x - \eta_y \cot \theta = 0 \quad [7a]$$

$$\xi_x + \xi_y \tan \theta = 0 \quad [7b]$$

From Equations [6], it follows that

$$\theta = \frac{1}{2} (\xi - \eta)$$

Equations [7] are, therefore, quasi-linear.

The characteristic equations of the system, Equations [7], are

$$\frac{dy}{dx} = -\cot \theta \quad [8a]$$

$$\frac{dy}{dx} = \tan \theta \quad [8b]$$

The characteristics satisfying Equation [8a] form the "first family of characteristics," and those satisfying Equation [8b] the "second family of characteristics."

Substitution of Equation [8a] into [7a] yields (9)

$$d\eta = \eta_x dx - \eta_y dy = 0 \quad [9]$$

Hence η is constant along each characteristic of the first family. Similarly, substitution of Equation [8b] into [7b] shows that ξ is constant along each characteristic of the second family.

Fig. 1 shows that the equations of the first and the second shear lines are identical to Equations [8a] and [8b], respectively. Hence the first and the second family of characteristics coincide with the first and the second family of shear lines.

BOUNDARY CONDITIONS

The proposed problem is indicated in Fig. 3. A sheet of material in the plastic state is drawn between two fixed cylindrical

FIG. 3

surfaces of radius R . These surfaces are assumed to be rigid. The thickness of the sheet is $2b$, and the angle which the normal at any point of the boundary makes with the negative y -axis is denoted by γ . Along the surface of the upper cylinder, for instance

$$\left. \begin{aligned} x &= R \sin \gamma \\ y &= b + R(1 - \cos \gamma) \end{aligned} \right\} \quad [10]$$

In the industrial practice the ratio b/R is of the order $1/200$. In order to obtain a clearer idea of the stress distribution, however, the ratio $b/R = 1/5$ will be used in the major portion of this paper. (For purposes of comparison with the results obtained by Sachs (1), the problem has also been solved for $b/R = 1/160$. The results are discussed in the next to the last section.)

The following boundary conditions are now prescribed:

(a) The exit section AB is assumed free from lateral compression, i.e., it is assumed that $\sigma_y = 0$ along AB .

(b) A uniform normal stress is assumed to be applied along AB .

(c) It is assumed that the shearing stress exerted by the walls on the plastic material is directly proportional to the normal pressure and acts in the direction of the relative velocity of the walls with respect to the material. From Fig. 4 it is clear that in our case the normal pressure $p = -\sigma_n$, where σ_n is the normal stress at the walls. Since no tension can be transmitted by the

walls, $\sigma_n \leq 0$ at all times. According to the sign convention used in Fig. 1, the direction of the applied shearing stress is positive. Hence $\tau_n = -f\sigma_n$, where τ_n is the shearing stress along the walls, and f is the constant coefficient of friction.

Fig. 4

On the other hand, according to the Saint Venant-Mises theory the shearing stress cannot exceed k , the yield stress in pure shear. The friction law at the walls should therefore be modified as follows

$$\left. \begin{aligned} \tau_n &= -f\sigma_n \text{ for } 0 < -f\sigma_n < k \\ \tau_n &= k \text{ for } -f\sigma_n \geq k \end{aligned} \right\} \dots\dots\dots [11]$$

From the definitions of θ and γ , it follows that the angle between the tangent to the boundary and the first shear direction is $\theta - \gamma + \pi/2$. The corresponding angle along Mohr's circle is $2(\theta - \gamma) + \pi$, and the stresses at the boundary are

$$\left. \begin{aligned} \sigma_n/k &= 2\omega - \sin 2(\theta - \gamma) \\ \tau_n/k &= -\cos 2(\theta - \gamma) \end{aligned} \right\} \dots\dots\dots [12]$$

Thus simultaneous solutions of Equations [11] and [12] determine the stresses at the boundary.

The state of stress at a boundary point is represented by a Mohr circle with the radius k . The location of the center of the circle depends upon the value of ω . Three representative positions of the circle are shown in Fig. 5.

Fig. 5

The graph of τ_n versus σ_n satisfying Equations [11] consists of a straight line parallel to the σ_n -axis for $\sigma_n \leq -k/f$, and a straight line passing through the origin with a slope equal to $-f$ for $-k/f \leq \sigma_n < 0$, as shown in Fig. 5. The points which this graph has in common with the Mohr circle (such as A and B, C and D) represent the solutions of the system Equations [11] and [12]. As seen from Fig. 5, the angle $\theta - \gamma$ for point B is greater than $\pi/2$. When $\theta - \gamma$ reaches $\pi/2$, the characteristics of the first family become tangent to the boundary and further increase in $\theta - \gamma$ is physically meaningless. Therefore for any given value of ω , the point A represents the only solution which has physical meaning.

Examination of Fig. 5 now yields the following ranges of $\theta - \gamma$:

$$\text{If } 2\omega \leq -1/f, \text{ then } \theta - \gamma = \pi/2 \dots\dots\dots [13a]$$

$$\text{If } -1/f < 2\omega \leq 1, \text{ then } \pi/2 > \theta - \gamma \geq \pi/4 \dots\dots [13b]$$

Elimination of σ_n and τ_n from the first Equations [11] and [12] yields, with the aid of Equation [6]

$$\gamma - \xi = -\beta - \frac{1}{2} \sin 2\beta - \cos 2\beta \dots\dots\dots [14]$$

where $\beta = \theta - \gamma$ and the coefficient of friction f has been set equal to 0.5.

The angle γ is known at any point on the boundary (see Equations [10]). If ξ is also known, Equation [14] can be solved for β . The result will fall into one of two possible cases:

(a) If a real solution does not exist, or if $\beta > \pi/2$, Equation [13a] applies. In this case

$$\theta = \frac{\pi}{2} + \gamma \dots\dots\dots [15a]$$

(b) If the solution is in the range $\pi/2 > \beta > \pi/4$, Equation [13b] applies. In this case

$$\theta = \beta + \gamma \dots\dots\dots [15b]$$

With θ and ξ now known, σ_n and τ_n can be computed directly using Equations [6] and [12].

SOLUTION IN THE REGION ABD

In this paper the term "solution" of Equations [7] shall mean a determination of the families of characteristics defined by Equations [8] and the conditions at the boundary. It has been shown in the section "Basic Equations," that ξ and η are constant along characteristics of their respective families. Thus once the characteristic field is determined, the values of both ξ and η are known at the point of intersection of any two characteristics. The stresses at this point are then easily computed from these values by means of Equations [6] and [4].

It will be shown in the next three sections of this paper that the solution of Equations [7] can be carried out separately in three well-defined regions in the plastic material. The first region consists of the right triangle ADB, Fig. 3, the second region of two curvilinear triangles ADE and BDH, and the third region of the rest of the plastic material between the rolls. The solutions in the first two regions are trivial in nature and are called "lost" solutions for reasons to be pointed out in a later section.

According to conditions (a) and (b) given in the section "Boundary Conditions," $\sigma_x = \text{const}$ and $\sigma_y = 0$ along AB, Fig. 3. From the yield condition Equation [1], it follows that τ is also constant along AB. Furthermore, at A the shearing stress $\tau = \tau_n = 0$, according to Equations [11], Equation [1] yields

$$\left. \begin{aligned} \sigma_x &= 2k \\ \tau &= 0 \\ \sigma_y &= 0 \end{aligned} \right\} \text{ along AB} \dots\dots\dots [16]$$

This makes AB the first principal direction. Consequently, θ is constant along AB and is equal to $\pi/4$. Also from Equation [3]

$$\omega = \frac{\sigma_x + \sigma_y}{4k} = \frac{1}{2} \text{ along AB} \dots\dots\dots [17]$$

Then, by Equations [6], ξ and η are constant along AB and, in turn, ω and θ are constant throughout the region bounded by AB and two rectilinear characteristics AD and BD. Thus ABD is a "region of constant stress." The first family of characteristics, corresponding to the first shear lines, consists of straight

lines parallel to AD . The value of η is constant along the characteristics of this family. The second family is formed by straight lines parallel to BD . The value of ξ is constant along the characteristics of this family. From Equations [6] it follows that

$$\left. \begin{aligned} \xi_0 &= \frac{1}{2} + \frac{\pi}{4} = 1.285 \\ \eta_0 &= \frac{1}{2} - \frac{\pi}{4} = -0.285 \end{aligned} \right\} \text{in region } ABD \dots \dots [18]$$

Note that Equations [7] are identically satisfied in ABD .

SOLUTION IN REGION ADE

Because of the symmetry of the stress distribution with respect to the x -axis, the remainder of the solution will be obtained only for $y \geq 0$.

The region ADE is bounded by a portion of the boundary AE , a characteristic of the first family AD , and a characteristic of the second family DE . All of the characteristics crossing AD from region ADB have the same value of ξ_0 . Therefore ξ is constant throughout region ADE .

From Equations [6] it follows that $\eta = \xi_0 - 2\theta$. Hence θ is constant along any characteristic of the first family. The characteristics are straight lines and their equations are found by direct integration of Equation [8a]. Thus

$$y = -x \cot \theta + f(\theta) \dots \dots \dots [19]$$

where $f(\theta)$ is to be determined from the boundary values which are given by Equations [10], [14], and [15]. Because of the transcendental nature of these equations, the following procedure is used in determining $f(\theta)$:

A graph of $\gamma - \xi$ is plotted versus β for the full range of β allowed by Equations [15]. Then for any given value of x , the corresponding values γ and y are determined from Equations [10] and, using $\xi = \xi_0 = 1.285$, the appropriate value of β is read off from the graph. The angle θ is then determined from Equations [15], and the value of $f(\theta)$ from Equation [19]. The value of ξ is constant throughout the region ADE . Equation [7b] is satisfied identically, and it remains to determine only the characteristic DE which forms a boundary of the region. Equations [8a] and [19] form a system of simultaneous equations

$$\frac{dy}{dx} = \tan \theta, \text{ and } y = -x \cot \theta + f(\theta) \dots \dots \dots [20]$$

where $f(\theta)$ is now assumed known. It is possible to eliminate x from these equations and to obtain an integral for y in a closed form.⁵ In the present problem, however, $f(\theta)$ is transcendental and it is simpler to solve the system, Equations [20], by step-by-step integration. The resulting characteristic is shown in Fig. 6 together with a few characteristics of the first family plotted for equal steps in γ . A characteristic family (such as shown in Fig. 6), consisting of nonintersecting straight lines, is said to form a "noncentered fan."

SOLUTION IN REGION PEDM BY METHOD OF FINITE DIFFERENCES

The following boundary conditions are prescribed in this region.⁶ Along the boundary EP Equation [14] must be satisfied. Along the characteristic DE the values of ξ and η are given. Along the x -axis τ must be zero for reasons of symmetry and therefore from Equations [4]

$$\theta = \frac{\pi}{4} \text{ for } y = 0 \dots \dots \dots [21]$$

Since both ξ and η vary in this region, Equations [7] and [8] no longer simplify and must be solved by an approximate procedure. Two alternative methods of solution have been used in this problem. The first, discussed in this section, consists of reducing Equations [7] to a system of linear difference equations. The second consists of constructing the characteristic families, Equations [8], by using approximate radii of curvature; it is taken up in the next section.

Equations [7] can be linearized by interchanging dependent and independent variables provided the Jacobian of the transformation.

$$\frac{D(\xi, \eta)}{D(x, y)} = \xi_x \eta_y - \xi_y \eta_x \dots \dots \dots [22]$$

⁵ Reference (4), p. 5.

⁶ This type of problem, in which the boundary is composed in part of a characteristic and in part of a geometric contour with a reflection condition, is known as the "mixed problem" in the theory of partial differential equations.

FIG. 6 GRAPHICAL SOLUTION USING APPROXIMATE RADIi OF CURVATURE FOR $b/R = 1/5$, $f = 0.5$

does not vanish identically in *PEDM*.⁷ Since ξ and η both vary in *PEDM*, this condition is clearly satisfied. The indicated transformation yields

$$y_{\eta} - x_{\eta} \tan \theta = 0, \quad y_{\xi} + x_{\xi} \cot \theta = 0, \dots [23]$$

where $\theta = (\xi - \eta)/2$.

To obtain the difference equations, assume that two intersecting characteristics have been determined completely, Fig. 7, and that from two arbitrary points $(k, l-1)$ and $(k-1, l)$, it is desired to construct two more characteristics up to their point of intersection at (k, l) . If points $(k, l-1)$ and $(k-1, l)$ are sufficiently close to $(k-1, l-1)$, Equations [23] can be replaced by the approximate expressions⁸

$$\frac{y_{k,l} - y_{k,l-1}}{\Delta \eta} - \frac{x_{k,l} - x_{k,l-1}}{\Delta \eta} \tan \frac{\theta_{k,l} + \theta_{k,l-1}}{2} = 0 \dots [24a]$$

$$\frac{y_{k,l} - y_{k-1,l}}{\Delta \xi} + \frac{x_{k,l} - x_{k-1,l}}{\Delta \xi} \cot \frac{\theta_{k,l} + \theta_{k-1,l}}{2} = 0 \dots [24b]$$

These equations are homogeneous in $\Delta \eta$ and $\Delta \xi$, respectively, and represent a system of two linear algebraic equations in three unknowns $x_{k,l}$, $y_{k,l}$, and $\theta_{k,l}$. The determination of these unknowns will differ somewhat depending upon the location of the point (k, l) . The following three cases have to be considered:

(a) Point (k, l) is on the line $y = 0$, Fig. 8. Then by Equa-

FIG. 7 A CELL OF CHARACTERISTICS

FIG. 8

tion [21], $y_{k,l} = 0$, $\theta_{k,l} = \pi/4$. Substitution of these values into Equation [24b] yields

$$x_{k,l} = x_{k-1,l} + y_{k-1,l} \tan \frac{\pi/4 + \theta_{k-1,l}}{2} = 0 \dots [25]$$

(b) Point (k, l) is inside the region, Fig. 7. From Equations [6]

$$\theta_{k,l} = \frac{\xi_{k,l} - \eta_{k,l}}{2} = \frac{\xi_{k,l-1} - \eta_{k-1,l}}{2} \dots [26]$$

Now let

$$\alpha_{l-1} = \frac{\theta_{k,l} + \theta_{k,l-1}}{2}, \text{ and } \alpha_{k-1} = \frac{\theta_{k,l} + \theta_{k-1,l}}{2}$$

Then Equation [24] yields

⁷ There are three distinct cases in which the Jacobian may vanish: (a), $\xi \equiv \text{const}$ in the region (b), $\eta \equiv \text{const}$. (c) ξ and η are both identically constant in the region. Cases (a) and (b) have been treated in the section "Solution in Region ADE;" (case b occurs in the region BDH and becomes identical to case a if ξ and η are interchanged in the equations). Case (c) has been treated in the section, "Solution in Region ABD." Since Equations [23] fail to provide solutions for these cases, they are termed "lost" solutions.

⁸ This procedure has been used by Sokolovsky (6) and Shevchenko (4).

$$x_{k,l} = \frac{x_{k-1,l} + x_{k,l-1} \tan \alpha_{k-1} \tan \alpha_{l-1} + (y_{k-1,l} - y_{k,l-1}) \tan \alpha_{k-1}}{1 + \tan \alpha_{k-1} \tan \alpha_{l-1}} \dots [27a]$$

$$y_{k,l} = \frac{y_{k-1,l} + y_{k,l-1} \tan \alpha_{k-1} \tan \alpha_{l-1} + (x_{k-1,l} - x_{k,l-1}) \tan \alpha_{l-1}}{1 + \tan \alpha_{l-1} \tan \alpha_{k-1}} \dots [27b]$$

(c) Point (k, l) is on the boundary, Fig. 9. There are now four unknowns: $x_{k,l}$, $y_{k,l}$, $\theta_{k,l}$ and γ ; and four Equations: [24a],

FIG. 9

two Equations [10], and [14]. Because of the transcendental nature of these equations, they are solved by the following procedure:

Starting from an arbitrarily selected point $(k, l-1)$, an estimate is made of $x_{k,l}$. Then γ and $y_{k,l}$ are computed from Equations [10], and $\theta_{k,l}$ is determined from the graph of Equation [14], with the aid of Equations [15]. Equation [24a] can be written

$$\tan \frac{\theta_{k,l} + \theta_{k,l-1}}{2} = \frac{y_{k,l} - y_{k,l-1}}{x_{k,l} - x_{k,l-1}} \dots [28]$$

The success of the approximation can now be checked by computing the r.h.s. of Equation [28], and comparing the resulting $\theta_{k,l}$ with the value obtained from the graph of Equation [14]. If the accuracy is insufficient, another estimate of $x_{k,l}$ is made and the entire procedure repeated.

Using the methods of solutions (a), (b), and (c), a network of points can now be plotted starting with the lower left corner of the region *PEDM* and extending as far as desired to the right. If continuous curves are now drawn through corresponding points, the two families of characteristics are obtained, and the solution is completed.

A running check on the accuracy of the computation is afforded by the orthogonal property of the characteristics (see Equations [8]). If at any stage the deviation from the 90-deg angle between two crossing characteristics is undesirably great, the size of the mesh can be decreased until the desired accuracy is reached.

The points computed by this procedure are indicated in Fig. 6 by small circles.

SOLUTION IN REGION *PEDM* BY USING APPROXIMATE RADII OF CURVATURE

The method used in the preceding section consists essentially of replacing the true curve of a characteristic by a sequence of straight-line segments. W. Prager (7) has recently suggested a method which approximates the characteristic by a sequence of circular arcs.⁹ This method improves the accuracy of the approximation and, in addition, represents a considerable saving in the computing time.

⁹ An alternative graphical method has been given by Prandtl (10). It has been used in parts of this problem where the curvature of the characteristics is small.

Again consider Fig. 7, and assume that the segment of the $\eta = \text{const}$ characteristic from point $(k-1, l)$ to point (k, l) is a circular arc. The length of the arc Δs and the radius R_η are related by

$$R_\eta = \frac{\Delta s}{\theta_{k,l} - \theta_{k-1,l}} \quad [29]$$

The arc length Δs is given approximately by

$$\Delta s = \overline{AB} \cos(\theta_A - \beta) \quad [30]$$

where \overline{AB} is the length of the straight line between A and B , and β is the angle between \overline{AB} and the negative y -axis. Also

$$\begin{aligned} \theta_{k,l} - \theta_{k-1,l} &= \frac{1}{2} [(\xi_{k,l} - \eta_{k,l}) - (\xi_{k-1,l} - \eta_{k-1,l})] \\ &= \frac{1}{2} (\xi_{k,l} - \xi_{k-1,l}) \end{aligned} \quad [31]$$

since

$$\eta_{k,l} = \eta_{k-1,l} \text{ and } \xi_{k,l} = \eta_{k,l-1}$$

Substitution of Equation [30] into [29] yields

$$R_\eta = \frac{2\overline{AB} \cos(\theta_A - \beta)}{\theta_{k,l} - \theta_{k-1,l}} \quad [32a]$$

and Equation [31] into [32a]

$$R_\eta = \frac{2\overline{AB} \cos(\theta_A - \beta)}{\xi_{k,l} - \xi_{k-1,l}} \quad [32b]$$

Identical procedure yields for the radius of curvature R_ξ of the $\xi = \text{const}$ characteristics

$$R_\xi = -\frac{\Delta s}{\theta_{k,l} - \theta_{k,l-1}} \quad [33a]$$

and

$$R_\xi = -\frac{2\overline{AB} \sin(\theta_A - \beta)}{\eta_{k,l} - \eta_{k,l-1}} \quad [33b]$$

In Equations [32] and [33] it is assumed that if ξ and η form a right-handed system of curvilinear co-ordinates, then positive values of R_η and R_ξ mean that the centers of curvature lie in the respective directions of increasing η and increasing ξ .

As in the previous section, computation will be different for the following cases:

(a) Point (k, l) is on the line $y = 0$, Fig. 8. In this case $\theta_{k,l} = \pi/4$, $\beta = 0$ and, because of symmetry with respect to the y -axis, $\overline{AB} = 2y_{k-1,l}$. The radius R_η is determined from Equation [32a].

(b) Point (k, l) falls inside the region. Equation [32b] and [33b] can be used directly.

(c) Point (k, l) falls on the boundary. Equation [33a] is used in conjunction with Equations [10] and [14]. A guess is made for the value of R_ξ and the corresponding arc is drawn to the boundary. Then Δs is measured, the co-ordinates (x_k, y_k) are read off, and $\theta_{k,l}$ is computed from Equations [10] and [14] as in the preceding section. Using Equation [33a], radius R_ξ is recomputed and the entire procedure is then repeated until satisfactory accuracy is obtained.

The field of characteristics for the region PEDM shown in Fig. 6 has been constructed by this method. At $x/b = 2.32$ the characteristics of the first family become tangent to the boundary, since β in Equations [15] reaches the value of $\pi/2$ and hence

$\theta - \gamma = \pi/2$. For $x/b > 2.32$ the boundary becomes an "envelope of characteristics."

RESULTS

Once the characteristic field has been mapped, the stresses at any point of the field are easily determined by the use of Equations [6] and [4], and the stresses at any point of the boundary by Equations [6] and [12].

Fig. 10 shows the stress distribution along the line $y = 0$, and Fig. 11 the distribution plotted versus the distance along the boundary. Figs. 12, 13, and 14 show the stress distribution computed along vertical cross sections taken at different points in the plastic material. The graphs show good qualitative agreement with the results obtained for the frictionless case by Sokolovsky (6) and Shevchenko (4).

FIG. 10 STRESS DISTRIBUTION ALONG x -AXIS

FIG. 11 STRESS DISTRIBUTION ALONG BOUNDARY

It was found that at the beginning of the region PEDM, the characteristics can be approximated closely by a single circular arc. This suggests that for small thickness-to-radius ratios the problem can be solved with sufficient accuracy by using a single circular arc to replace the entire segment of a characteristic extending from the center line to the boundary. In addition if the total angle of grip γ_{\max} does not exceed 10 deg, the transcendental friction law at the boundary given by Equation [14] can be linearized, thus simplifying case (c) of the preceding section.

With these simplifications the problem has been solved graphically using $b/R = 1/160$ and boundary values of the section, "Boundary Conditions." The resulting stress distribution is shown in Fig. 15. At $x/b = 12$, the horizontal stress along the y -axis is $\sigma_x/k = 0.20$, and the normal stress at the boundary is $\sigma_n/k = -1.8$. Sachs(1) gives $\sigma_x/k = 0$, and $\sigma_n/k = -2$ for $x/b = 12$.

DETERMINATION OF PLASTIC-ELASTIC BOUNDARIES

The process of forming a sheet between fixed guiding surfaces will be one of the following three cases:

 FIG. 12 STRESS DISTRIBUTION ALONG VERTICAL SECTION AT $x/b = 1.38$

 FIG. 13 STRESS DISTRIBUTION ALONG VERTICAL SECTION $x/b = 2.32$

 FIG. 14 STRESS DISTRIBUTION ALONG VERTICAL SECTION $x/b = 3.0$

(a) *Pure Drawing.* In this case a drawing force is applied to the sheet at the exit from the guides, but no force is applied at the entrance.

(b) *Drawing Under Tension.* A drawing force is applied at the exit and a smaller tensile force at the entrance.

(c) *Extrusion.* In this case a compressive force is applied at the entrance and no force at the exit. For the purpose of determining the boundaries between the plastic and the elastic portions of the sheet the three cases may be summarized by requiring that a prescribed resultant horizontal force, say, F_{AB} , be applied to the plastic region at the exit from the guides and another horizontal force, say F_{PQ} , be applied to the plastic region at the entrance.

A material behaving according to the Saint Venant-Mises theory remains rigid up to the yield point. As a result of this, the entire section of the sheet between the guides must be in a plastic state. Consequently the plastic-elastic boundaries must pass through the points of the boundary (such as P , Q and A , B in Fig. 3), at which the sheet enters and leaves the guides.

 FIG. 15(a) STRESS DISTRIBUTION FOR $b/R = 1/160$, $f = 0.224$

 FIG. 15(b) GRAPHICAL SOLUTION FOR $b/R = 1/160$, $f = 0.224$

On the other hand, the resultant horizontal force transmitted across the boundary from the plastic to the elastic regions of the sheet¹⁰ must be equal to F_{AB} and F_{PQ} at the two respective boundaries. This condition is satisfied automatically at the exit by the method of solution used in this problem. It may be satisfied at the entrance to the guides by the following procedure:

Horizontal stress distributions, such as in Fig. 12, are plotted for a number of vertical sections in the plastic material. By interpolating between adjacent sections, a section is located along which

$$2 \int \sigma_x dy = F_{PQ}$$

integration being carried out from the center line to the boundary. If P and Q are used to denote the points at which this section intersects the boundary, then for any curve C joining P and Q through the plastic material

$$\int \sigma_s ds = F_{PQ}$$

the left side representing a line integral along C . This relation is easily seen by considering the horizontal equilibrium of a region such as $PMQN$ in Fig. 3. If the initial thickness of the sheet is now made equal to PQ , any such curve C will satisfy the conditions imposed on the plastic-elastic boundaries.¹¹ Thus the thickness of the sheet which may be formed under the con-

¹⁰ The transmitted shearing force will automatically be zero by the symmetry of the shearing stress distribution with respect to the x -axis.

¹¹ Determination of the actual shape of the plastic-elastic boundary curve depends on kinematic as well as dynamic considerations and is too involved to be attempted here.

ditions of this problem is uniquely determined for any prescribed system of loading.¹²

- 12 It is important to keep in mind that this problem is solved under the assumption of negligible inertia forces. Thus the thickness determined in the foregoing represents the maximum thickness of the sheet which can be formed by the prescribed forces. If the thickness is smaller than the maximum, the sheet will accelerate, and the present solution is no longer applicable. If the thickness is greater, the sheet cannot be formed by the prescribed forces.

Motor-Generator Locomotives, Their Design and Operating Characteristics

By J. C. FOX,¹ J. F. N. GAYNOR,² AND F. D. GOWANS³

The motor-generator type of locomotive permits the application of the direct-current series-wound traction motor, with its highly desirable characteristics, to electrifications deriving their power from a single-phase alternating-current trolley. This is of particular benefit in the operation of heavy-drag freight trains on mountain grades. Nearly 30 years of design and operating experience have gone into the development of this type of locomotive. The latest examples are the units recently placed in service on the electrified sections of the Great Northern and Virginian Railways. Noteworthy features in the design, construction, and operation of these units are discussed.

GENERAL CHARACTERISTICS

IN heavy-drag freight-train service, encountered in mountainous territory, involving relatively long and heavy gradients, the direct-current series-wound motor has much to recommend its use. In addition to relative simplicity of construction, the series-wound motor has the characteristic ability of producing, without appreciable damage to itself, high initial torques without accompanying armature rotation—a characteristic which finds practical utilization when the motor is used in a locomotive that is required to “lay up” against a heavy train in the effort of getting the train under way.

The drop in speed and rapid increase in torque of the series motor as its loading is increased, with the accompanying tendency to maintain, to a certain extent, a relatively constant load on the power source, make this type of motor well suited for traction purposes.

On the other hand, the presence of a commutator on the motor armature restricts the voltage which can be used across the motor to a relatively low value, as transmission and distribution voltages are judged. Hence the desire to employ a high voltage on the contact system is accompanied by the necessity of using a transforming medium between the contact line and the traction motors if these be of the direct-current series-wound type. To date the highest practicable contact-line voltage for direct application to the direct-current series-wound motor is something less than 4000 volts, with the application made by connecting two motor armatures permanently in series and gearing them to a common gear on the driving axle. Thus with something less than 2000 volts per motor armature, valuable space is required for conductor insulation, and this space might better be used for active material, i.e., copper and iron, to secure the maximum output from the restricted spaces in which traction motors are

required to work. This is done by the use of relatively low-voltage motors, such as are used in the motor-generator and Diesel-electric types of locomotives.

There is no practically usable static transformer-rectifier combination commercially available to the locomotive builder that will transform high-voltage alternating-current single-phase energy to low-voltage direct-current energy suitable for use with the simple direct-current series-wound motor in traction service. The mercury-arc rectifier, in recent years, has been viewed as a possible candidate for this role. Corrective measures must be taken to minimize primary-power-supply wave distortion, characteristic of single-phase-rectifier operation. Interference must be reduced to values acceptable from the viewpoint of communications-lines interference, which would render this type of transformation unacceptable from the locomotive builder's and operator's point of view.

The alternating-current synchronous-motor direct-current generator set, in combination with a suitable static transformer of the conventional alternating-current type seems to be the most practicable means of energy conversion for locomotive use where direct-current series-wound traction motors are employed.

Hence the motor-generator type of locomotive and its justification in heavy traction service.

ADVANTAGES

There are several incidental but valuable advantages attendant upon the use of the synchronous-motor-generator locomotive. These may be cited as follows:

- 1 The maintenance of power factor in the railroad-owned transmission and distribution lines at values close to unity, and, in some cases, of leading power factors, is practicable by the control of the synchronous-motor excitation.

- 2 The motor-generator locomotive is essentially a constant-horsepower machine and, accordingly, the avoidance of large power demands under heavy grade or accelerating conditions is of direct benefit to the operating company's power bills, as influenced by peak-demand charges.

- 3 The motor generator set and its control lend themselves to flexibility of control functioning during regenerative-braking and motoring periods, with a consequent flexibility of locomotive and train control.

- 4 The performance characteristics of the locomotive are independent of contact-system voltage drop, down to a limit dictated by synchronous-motor pull-out torque.

- 5 The performance characteristics of this type of locomotive appear to be admirably suited to the operation of railroads traversing long stretches of terrain at river grade, interrupted with severe mountain gradients of appreciable length. Thus relatively fast schedules are secured for a limited given power demand.

- 6 Because the motor-generator locomotive is, to a large extent, similar to the Diesel-electric in that both employ driven direct-current generators and associated traction motors, the same design of traction motor can be used in both types of locomotives. Thus the benefits of standardized production of

traction motors are available to the operator of motor-generator locomotives.

HISTORY

The motor-generator locomotive is not a recent development. The first one built in the United States was an induction-motor-generator unit operating under a 2300-volt 60-cycle single-phase overhead-contact system. This was in the nature of an experimental locomotive built by General Electric in 1910, for a small privately owned railroad desiring to use the commercial form of energy available to it without conversion apparatus. The line has long since been abandoned.

In the middle 1920's the New Haven Railroad purchased five 1120-hp, 1-B+B-1, 138-ton motor-generator freight locomotives, Fig. 1, and two B+B, 100-ton switching locomotives of the same rating (1).⁴ These were built for use in electrified territory where contact-system power-factor correction was an objective.

When the Great Northern Railway relocated its line through the Cascade Mountains in the late 1920's, a relocation which involved the abandonment of operation through the old 2.75-mile Cascade Tunnel and the driving of a new bore 7.79 miles in length, 15 years of operating experience with the then existing 6600-volt three-phase electrification indicated that a more flexible system was desirable for the new section of line. Accordingly, the 11,000-volt 25-cycle single-phase system, with motor-generator locomotives, was adopted (2, 3).

The first locomotives purchased for the new electrification

⁴ Numbers in parentheses refer to the Bibliography at the end of the paper.

were built by Baldwin-Westinghouse as 1-D-1, 179-ton, 1830-hp (cont.) 2165-hp (one-hour) units, operable in multiple in combinations of two to five cabs, see Fig. 2, under the control of one engineman (4). These were supplemented by a 1-C+C-1, 270-ton, 3000-hp (cont.) 3300-hp (one-hour) design built by American Locomotive and General Electric, shown in Fig. 3, also capable of being operated in multiple to provide large concentrations of motive power under the control of a single engineman (5).

NEW LOCOMOTIVES

Early in 1947 the Great Northern took delivery from the General Electric Company of two B-D+D-B, 360-ton, 5000-hp single-cab locomotives, Fig. 4, bringing the total number of units now operated by this railway to twenty (6).

Table 1 gives dimensional and other salient characteristics of the locomotives composing the Great Northern fleet.

With the delivery in the early part of 1948, of four 6800-hp double-cab 500-ton locomotives (7), the Virginian Railway became the fourth⁵ railway in the United States to operate this type of motive power. These locomotives, with somewhat more than a million pounds on drivers, classify as the heaviest (in so far as driver weight is concerned) and the most powerful continuously rated electric locomotives in service in the United States.

Principal characteristics of the Virginian locomotives are shown in Table 2, and one of the units is shown in Fig. 5, at the

head of a 6000-ton train of loaded coal cars on a 2 per cent grade, with an induction-motored locomotive as a helper at the rear.

It is the purpose of this paper to discuss design features of and operating results secured with the latest Great Northern and the Virginian locomotives. Each of the designs is unique in that the former is the longest single-cab electric locomotive ever constructed, while the latter is the first design of electric locomotive to carry a million pounds on drivers. The design of both locomotives involved problems not heretofore encountered in locomotive-development work.

BASIC DESIGN CONSIDERATIONS

Basic requirements in the case of the Great Northern locomotive were as follows:

- 1 A total of 5000 hp at the rail at a continuous rating, to be available continuously at a low speed of between 15 and 20 mph.
- 2 Locomotive to be built in a single-cab unit.
- 3 All weight to be on drivers.

The specification of 5000 hp at the rail indicated a synchronous-motor rating of 6000 hp, with an over-all electrical-transmission efficiency, between the synchronous motor and rail, of approximately 83.5 per cent. Synchronous-motor design factors, restricted by a permissible stator diameter of 83 in., which allowed a 17 in. width of aisle and 3 in. for each cab-wall thickness, and a synchronous speed of 750 rpm, made necessary the use of two separate set driving motors, each having a continuous rating of 3000 hp.

Similar restrictions, applying to traction-generator design, resulted in the use of two generators to be driven by each of the synchronous motors.

The traction motor which was selected is the GE-746, a standard series-wound motor originally designed for Diesel-electric locomotive applications with maximum axle loading of 60,000 to 62,500 lb on 42-in-diam wheels with 65 mph (top speed) single-reduction gearing. The motor is rated as being suitable for use with a traction generator involving 500-hp input from the prime mover (in this case, the synchronous motor) per traction motor. Thus for a synchronous-motor rating of 6000 hp, twelve traction motors, with a total locomotive weight of 720,000 to 750,000 lb, were indicated.

With these design elements fixed, the over-all problem resolved itself into one of designing a running gear with twelve motored axles that would negotiate 10 deg main-line curvature coupled to trains and 17 deg wye trackage alone, and that would match with a double-end cab of sufficient length to house the two 3000-hp three-unit motor generator sets and their associated auxiliary and control equipment.

Preliminary specifications for the Virginian motive power stipulated a continuous rating such as to permit the haulage of trains as large as those being handled by the three-cab 6000-hp induction-motored locomotives with which the railway has been operating since the electrification of the Mullens-Roanoke section of its line.

The impracticability of mounting so large a rating in a single cab was obvious at the outset and a two-cab locomotive was selected as the basis of design.

A study of the service requirements and the performance of the existing motive power indicated that a locomotive carrying approximately a million pounds on drivers would be required. Since the top speed involved (50 mph) was moderate, it was decided that all weight would be on drivers and no special guiding axles would be required.

The desire to utilize the GE-746 traction motor, with a permissible axle loading of 62,500 lb with maximum reduction gearing resulted in the selection of sixteen motored axles, eight of

which were to be located under each of the two cabs. The use of sixteen traction motors, each rated for 500-hp input to the traction generators, fixed the total continuous synchronous-motor capacity at 8000 hp, or two 4000-hp sets. Transmission efficiencies permitted a rail-horsepower rating of 6800 at the speed at which maximum continuous tractive effort of the traction motors occurs.

The selection of an eight-axle running gear for each of the two cabs was narrowed down to two designs, a B-D-B arrangement employing a main frame, integral with the cab structure, and two two-axle swivel trucks; or a B-B-B-B arrangement, employing four identical two-axle swivel trucks.

The second arrangement was selected in the interests of easy maintenance, interchangeability of trucks, and over-all superior flexibility of operation. The resulting locomotive nomenclature of this arrangement of running gear is 2 (B-B-B-B), and each of the two units composing the locomotive is, for all practical purposes, a duplicate of the other. One unit, however, carries two pantographs (one being a spare collector), while the second carries but one. A second collector may be added to the second unit if operating experience indicates this to be advisable.

CAB DESIGN

In conformity with current appearance styling practices, the cabs of both locomotives have been streamlined, combining appearance with practical utilization of space and good visibility. Nose compartments and operating cabs are practically identical in both designs. A full-size model of these portions of the cabs was made before construction to determine characteristics.

For optimum visibility with a long hood or "nose" section, a 16-ft radius over the cab roof from the track center line at a rail level was used, which results in positioning of the operator's eyes but a few inches below the maximum at the cab center line. The right-hand running rail can be seen from normal eye level at a distance 50 ft ahead of the coupler.

The top of the hood extending down to the level of the window sill is made up on a three-piece form, two outside sections—left and right—and a center section. By changing the width of the center section the form is made suitable for cabs of different widths, within certain limits of course. From the window sill to the bottom of the cab the hood sheets are perfectly straight, cut on a bias, and wrapped around the hood. Above the sills the windows and cab side sheets have been drawn in at an angle of 15 deg. This was done for appearance reasons only in this case, to set off the superstructure from the side sheets and relieve the otherwise boxy appearance. However, in a number of other instances this has been done to meet clearance restriction and is quite practical. On both locomotives the striping and lettering have been arranged to relieve the side-sheet expanse and embrace the air-inlet grilles.

PLATFORM DESIGN

Although the outward appearances of these locomotive cabs, as shown in Figs. 6 and 7, are very similar, the supporting structures are quite different. This is due chiefly to the horsepower requirements for a single-cab unit. A unit of the Virginian locomotive rating 4000 hp represents the practical maximum rating of a single motor generator which can be accommodated in the width and height available, even though both locomotives are unusually high and wide. The Great Northern locomotive, requiring 6000 hp in a single unit, would not accommodate a set this large, and the cab had to be stretched out to accommodate two 3000-hp sets end to end, as shown in Fig. 8. For this reason the cab is long, with a center-plate distance of 56 ft 6 in. This determined the nature of the structure, which is a truss designed to keep the deflection within design limits.

FIG. 6 GREAT NORTHERN 5000-HP MOTOR-GENERATOR LOCOMOTIVE

FIG. 7 VIRGINIAN 6800-HP MOTOR-GENERATOR-LOCOMOTIVE

FIG. 8 CROSS-SECTIONAL ELEVATION OF 5000-HP GREAT NORTHERN LOCOMOTIVE

The truss supports a central equipment platform with end bulkheads, intermediate cross-ties, and lateral bracing. Fig. 9 shows center of gravity and weight distribution. The symmetry of cab and truss construction, together with equipment location from each end to the center, results in unusually good weight distribution.

On the Virginian locomotive, Fig. 10, the center-plate distance is shorter, namely, 34 ft 6 in., permitting the use of a suitably deep platform instead of a truss. The main sills are 24 in. deep between the bolsters and reduce to 18 in. for the end extensions.

Procurement of the desired weight distribution on the Virginian

locomotive was difficult because the large pieces of equipment (motor generator set and transformer) necessarily were forced to the rear by the single-end operating cab and hood. Since the railway desired to avoid the use of loading pads between the cab and truck, all the cab weight had to be carried on the two center plates. By very careful arrangement of equipment, proper weight distribution was secured. The preliminary loading diagram, Fig. 11, shows the center of gravity of the cab only 1 in. to the rear of the center line, and the rear center-plate load only 1730 lb heavier than the front one. The matter of span bolster weight distribution had to be considered since the front

FIG. 9 WEIGHT-DISTRIBUTION DIAGRAM FOR GREAT NORTHERN UNIT.

FIG. 11 PRELIMINARY WEIGHT-DISTRIBUTION DIAGRAM FOR THE VIRGINIAN LOCOMOTIVE

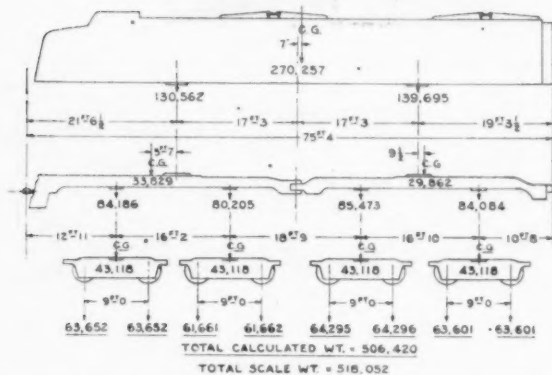

FIG. 12 FINAL WEIGHT-DISTRIBUTION DIAGRAM FOR THE VIRGINIAN LOCOMOTIVE

bolster was longer and carried the pilot and draft gear on the extreme end.

A study of the loading diagram indicates the truck arrangement employed to balance these loads. Since the actual expected weight was not known until some time after the design dimensions were fixed, the weight distribution actually secured was remarkably close to calculations, even though a difficult time was encountered with the first locomotive weighed. When it was weighed, there was 10,000 lb weight difference between the

FIG. 10 CROSS-SECTIONAL ELEVATION OF 6800-HP VIRGINIAN LOCOMOTIVE

heavy covered drawing were of actual

Fig. locomotives passenger posts an ultimate bottom withstanding sufficient 18 in. These attached at the sills. sheets This structural limits within framing of each

heaviest and the lightest axles.' Upon investigation it was discovered that some equalizer springs which were not within the drawing tolerances had been used, and both cab center plates were out of alignment. The final calculated weights and the actual weights secured by weighing are shown in Fig. 12.

Fig. 13 shows the collision structure of the Great Northern locomotive. It is designed to meet AAR specifications for new passenger cars. The sum of the section moduli of both vertical posts and their reinforcement is 66.75 in.³ Each post has an ultimate shear value of 316,800 lb where it is attached at the bottom to the underframe. The top attachment is designed to withstand a force of 27,800 lb when the post is subjected to a force, sufficient to develop the yield point of the material, of 85,500 lb, 18 in. above the bottom attachment.

These posts are further strengthened by means of plates attached to the top and running diagonally to the side structure at the corners of the front bulkhead, at the level of the window sills. On the outside the contour of these plates follows the hood sheets and provides a connection for the top and side hood sheets. This structure is expected to withstand collision forces within the limits indicated, yielding as the forces increase but absorbing them within limits to protect personnel and equipment. Collision framing with this same stiffness is provided at the front and rear of each of the Virginian cabs.

TRUCKS

Here the two designs are widely divergent. As has been noted previously, the number of axles was determined in each case by the performance specifications and the selection of a particular traction motor to meet speed-tractive-effort requirements. The GE-746 motor rating 500 hp, on the basis of output from the synchronous motor, dictated twelve motored axles on the Great Northern and sixteen (eight per unit) on the Virginian machines.

The use of simple swivel two-axle trucks, supporting span bolsters and cab, was made possible on the Virginian locomotive by the comparatively low top speed specified. Span bolster and truck frames are of grade A unannealed cast steel. The truck frames are supported on double equalizers, which span the journal boxes, by means of helical and semielliptic springs. Loads are proportioned on the springs in the ratio of 65 to 35, respectively. The wheels are rolled steel, class C, 42 in. diam. They are pressed on axles which have $7\frac{1}{2}$ -in. \times 13-in. journals equipped with roller bearings. No restraining or guiding devices were required. All trucks are completely interchangeable in either direction.

Requiring twelve axles to carry the single cab, the design of the Great Northern unit presented a number of new and interesting problems.

In considering running gear and wheel arrangement, the 2-C+C-2 arrangement had been employed a number of times very successfully. It has ten axles but only six drivers. To obtain the required number of drivers with an arrangement similar to this it was necessary to increase the length of the main truck to accommodate four axles instead of three and apply motors to the guiding axles. Such an arrangement is classified as B-D+D-B.

With the wheel arrangement settled, the next problem was to determine the length of the four-axle main trucks. The rigid wheel base of this truck developed to be 16 ft 9 in. long. To accommodate the maximum lateral displacement ($1\frac{1}{2}$ in. each way required at the two inside axles on the 17-deg curve), the thickness of the pedestal was reduced at these points in order to maintain identical journal boxes, and a device made up of three layers of rubber vulcanized to intermediate layers of steel on top of each journal box was used. This device was designed to permit the required displacement at a force approximating 10 per

FIG. 13 COLLISION POST CONSTRUCTION EMPLOYED IN NOSE OF LOCOMOTIVE CAB

FIG. 14 GUIDING-TRUCK RESTRAINT AS USED ON THE GREAT NORTHERN UNIT

cent of the journal load. This force is sufficient to restore the axle to its normal position and maintain stability on a tangent track.

The over-all length of the running gear was approximately 3 ft shorter than the cab, making it necessary to use a drawbar between the main trucks instead of an articulation.

The loading pads required at the rear of each main truck to obtain proper load distribution required loading to 28,100 lb each on four pads.

Motored guiding-truck axles required the same-size wheels and the same load as the main-truck axles. Consequently the bolster and centering devices had to be designed for these loads.

A number of restraining devices were required to guide and

stabilize the running gear. Most interesting of these is the guiding truck bolster restraint shown in Fig. 14. The restraining forces are determined by the weight on the center plate and the slope of the roller plates. To guide the main truck around the curves, sufficient resistance is designed into the guiding-truck bolster restraint to slip the leading wheels of the main truck from flange contact with the outside rail to flange contact with the inside rail. Since centrifugal force enters into the calculation of the forces, the final design had to be a compromise between high-speed and low-speed conditions. A spring restraint is used between the guiding truck and the main truck to stabilize the guiding truck on tangent track. Between the two main trucks there is another spring restraint to guide the trailing main truck around the curves. It is designed with sufficient force to slip the leading wheels of the trailing main truck from flange contact with the outside rail to flange contact with the inside rail.

Both the Virginian and Great Northern locomotives are equipped with cast-steel pilots. Fortunately, it was possible to design both truck frames for the same pilot. The nature of these roads, following mountain streams and slopes, subject them to numerous snow and rock slides. Strong, heavy pilots many times have prevented derailment and other damage by being able to withstand and push aside the smaller slides.

VENTILATION

Equipment ventilation always affects, and therefore must be considered in, the mechanical design. The unusual air requirements (100,000 cfm for the Great Northern and 82,000 cfm for a single unit of the Virginian) made evident the seriousness of the problem at the beginning. A factor which led to a solution of this problem was a means for starting the single-phase synchronous motors. It is desirable, because of the power and additional equipment involved in single-phase alternating-current starting, to employ other means of bringing the motor up to approximately half-speed before applying alternating-current power. Means used previously were not considered altogether satisfactory. Further investigation led to the use of a small motor generator set for furnishing starting power. This set, driven by a single-phase 1500-rpm induction motor driving a direct-current generator, could be used to motor the main generators and thereby start the synchronous motor. It could have a very high short-time rating sufficient for main-set starting purposes, and a continuous rating sufficient for control and battery charging during normal operation. In order to take advantage of the simplicity and ruggedness of the induction motor for auxiliary drives, a three-phase synchronous generator was added to the starting set, making it a three-unit two-bearing set, and power was thus secured to operate induction-motor-driven blowers. Combinations of the synchronous-generator and induction-motor poles give the desired blower speeds. In general, a ten-pole generator and four-pole motors to give a motor speed of 3600 rpm have been used. This relatively high speed secures advantages in both space and weight. Another advantage in the use of this system is the simplicity of its control. The generators are designed so that all blowers can be started at once by simply closing the generator-field contactor.

Characteristics of the high-speed axial-flow blower are admirably suited for locomotive applications. Combining high flow and pressure in relatively small space, it has been used to great advantage on both of these locomotives. On the Virginian motive power, where fine coal dust, water, and dirt are a constant menace to electrical equipment; air cleaning blowers, forced ventilation for the main motor generator set, and air taken directly from the outside instead of from the apparatus cab, were specified. A mechanical cleaning device forming the blower inlet was developed and tested. The results indicated as much

as 75 per cent efficiency under standard test-code conditions.

Of special significance on the Great Northern electrification is the operation through the Cascade Tunnel. Temperature in the tunnel is practically constant at 55 F. To avoid condensation of moisture on the electrical equipment when entering the tunnel from a colder outside temperature, means are provided for recirculating the transformer and motor generator set cooling air. By recirculating this air, the machine temperatures can be kept above the dew point.

AIR BRAKES

Both designs of locomotives employ type 8EL air-brake equipment. Requiring overspeed control, the Great Northern unit uses the KS-8-PB brake valve, while the Virginian locomotive uses the plain K-8-PA valve. The Virginian machines, handling 9000-ton trains, require higher compressor and reservoir capacity than the Great Northern units. Each cab of the Virginian locomotive is equivalent in air-compressor capacity to the Great Northern, having two motor-driven compressors with a total displacement of 300 cfm and reservoir capacity of 75,000 cu in.

Foundation brakes on the Great Northern locomotive are designed to use a single shoe on each wheel. Each cylinder on either side of the truck serves two axles. The same braking ratio (70 per cent at 50 psi cylinder pressure) is used on both the guiding and main-truck axles. A conventional clasp brake is used on the Virginian design. The braking ratio is 75 per cent at 50 psi cylinder pressure.

OPERATION OF THE GREAT NORTHERN

Since the Great Northern has been operating motor-generator locomotives in its electrified territory since 1926, the new locomotives initiated in 1947, were not novel in so far as type is concerned. As a consequence the introduction of the new locomotives into service involved primarily an extension of well-established operating methods, taking into account the greater ratings and capabilities over the older motive power.

The electrified section of the Great Northern has been described in numerous articles appearing in the technical press (3, 4, 5), and a detailed description of the installation is outside the scope of this paper. It will be well to note here, however, that operation involves gradients of 2.2 per cent and a tunnel approximately 8 miles in length, with the line running through mountainous territory subjected to heavy snowfalls and a temperature range between -20 and +110 F. The profile of the line is shown in Fig. 15.

Preliminary tests on the locomotives indicated a freight-train tonnage rating of 2000 to 2100 tons as a continuous loading on the 2.2 per cent grades. Scaled-weight trains of these tonnages on the 2.2 per cent grades loaded the locomotive traction motors to continuous-rating values, indicating total tractive effort of 123,000 lb at a continuous speed of 15.75 mph. Thus the rail horsepower delivered at continuous rating developed to be 5160 hp. Starting tests on these grades developed adhesions of 26.5 per cent and accelerations were accomplished quite readily without the use of sand on clean dry rail.

With full-rated tonnages, the locomotives are worked at adhesion values approximating 17 per cent on tangent track with dry rail, and there appears to be little, if any, tendency for driving wheels to "creep" under these conditions. Some creep is experienced in entering and leaving curvature. With poor rail conditions some creep with no attendant loss in train speed is experienced on tangent track. In heavy curvature, however, the degree of creep encountered results in train-speed loss of 1 to 2 mph. Average all-weather running adhesions of 15 per cent to 16 per cent on track, involving curvature of 8 deg to 10 deg, have been found to be practicable.

FIG. 15 CONDENSED PROFILE OF ELECTRIFIED SECTION OF THE GREAT NORTHERN RAILWAY

No noticeable differences in operable adhesion values as affected by driving-wheel diameter have been observed. The new locomotives have 42-in. drivers while the older machines have 55 to 56-in.-diam driving wheels.

The extreme fineness of control afforded in both motoring and regenerating operations permits the ready use of the new locomotives in freight trains with any type of motive power operated, be it steam, Diesel-electric, or the older types of motor-generator electric locomotives. Heavy freight operations involving trailing tonnages of 5000 tons are worked with locomotives at the head end, in the middle and at the end of the train.

Passenger trains with consists of 14 to 17 Pullmans and a heating tender (the locomotives are not equipped with train-heating boilers) are handled up to speeds of 50 and 60 mph consistent with track limitations and passenger comfort.

While the motor-generator locomotive is basically a constant-horsepower machine, lending itself nicely to the practice of peak-demand control by power dispatchers, it can be overloaded for short times as occasions and emergencies demand. Rail horsepower approximating 5800 have been secured on occasion from the new locomotives.

Power-factor control of the supply system is readily obtained by manipulation of the synchronous-motor excitation on all of the motor-generator motive power. Unlike the Virginian Railway operation, no induction-motored locomotives are operated, and the maintenance of unity to 0.95 leading power factor on the system is readily accomplished.

The efficiency of operation measured in terms of gross-ton-miles per hour seems to be somewhat better for the new locomotives than for the older units. A figure of 6.8 gross-ton-miles per hour per kilowatt at the substation on a 2.2 per cent grade holds for the new machines compared to 6.2 gross-ton-miles per hour per kilowatt for the average performance of the older machines. Undoubtedly, this is due in part to the lesser weight per horsepower of locomotive 147 lb applying to the new locomotives, compared to 180 and 203 lb for the older machines. The new locomotives have all the weight on the drivers.

The use of the B—D+D—B running gear with four motored axles in each of the main-truck frames gave rise to some question as to the effect the locomotives might have on the track structure. Observations during initial operations indicated that good tracking was being secured over the whole range of speeds operated. However, shortly after operation had commenced, some sections of track were rebalanced in routine maintenance, and complaints developed that the locomotives were moving track in sharp curvature.

Measurements were made which indicated no deflection at speeds above 30 mph. However, at speeds of 10 to 15 mph permanent deflections of the track toward center of curvature, as much as 1/2 in. were recorded, when drivers Nos. 3 and 10 moved by the recording point. These observations indicated that the initial resistance (24 per cent) of the variable-resistance centering device was too high. Pending installation of new roller plates, temporary relief was secured by removing the wear plates from the journal boxes and pedestals on drivers Nos. 3 and 10 which increased the lateral to approximately 1 1/2 in.

New roller plates were supplied which reduced the initial resistance to 18 per cent, building up to 20 per cent in the first inch. With these changes, the locomotives have been operating satisfactorily.

Some interesting observations of the added train resistance occasioned by the "piston action" of trains in long tunnels have been made. Comparing train-power demands, as indicated by the locomotive metering equipment, approximately 7 per cent more power in motoring is required to move a train against the tunnel grade than is required for operation at the same speeds on open grades of the same severity. The amount of regenerated energy is affected to the same degree, and less energy is required to hold a train at given speeds in the tunnel than is required for similar grade and speed conditions in the open.

Observations involving the added train resistance occasioned by 4 to 6 in. of snow on the tracks indicate an increase of resistance of approximately 15 per cent.

A minimum of rail sanding is employed since tests indicate that train resistance may be increased by as much as 10 per cent by the over-liberal use of sand in making train starts with heavy trains on heavy grades.

OPERATION ON THE VIRGINIAN

The electrified section (9) of the Virginian's lines extends eastward from Mullens, W. Va., to Roanoke, Va., a distance of 134 miles, traversing heavy mountainous territory crossing the Appalachians with a maximum ruling grade eastbound of 2.07 per cent. The profile of the electrified section and data pertinent thereto are shown in Fig. 16. The line is single-tracked with the exception of 22 miles of double track eastward from the Mullens terminus. The 11,000-volt 25-cycle single-phase system was installed in 1925, and, until the recent acquisition of motor-generator locomotives, has been operated with two-speed (constant speeds at 14 and 28 mph) 6000-hp induction-motored locomotives (10).

The two-speed induction-motored locomotives were entirely

alternating-current series commutator motor, and the other the direct-current series motor. For traction circuits the former uses a step-down transformer with a number of secondary taps to provide the range of voltages required for acceleration and running; the latter uses a step-down transformer with a minimum number of secondary taps for supplying proper voltage for the synchronous motor which drives the direct-current generator. From the standpoint of amount of major equipment and control required, the locomotive using the alternating-current series traction motor is the simpler. The offsetting feature, however, of the motor-generator type of locomotive is its use of the standard railway type direct-current series traction motor.

Granted that both types of locomotives can be built to produce the general operating characteristics required, the long-range factor of cost of maintenance and cost of operation in respect to power consumed must be considered.

While the modern motor-generator locomotives described in the paper are too new as yet to judge what their maintenance cost will be, nevertheless, it would be reasonable to suppose that over the life of the locomotive it would be higher for the motor-generator type than for the other type. Certainly it would be interesting and valuable to follow this feature in connection with these locomotives.

As to the power-consumption question, it would be expected that the motor-generator-type locomotive would entail more losses than its alternating-current traction motor counterpart, though admittedly this particular feature would be in some degree offset by power-factor correction.

Certainly the experience of the New Haven Railroad with motor-generator-type freight and switching locomotives, starting in 1926, points to the significance of both of these questions, of maintenance and power consumption.

The authors have done a fine job of describing the design and operating characteristics of the latest motor-generator-type locomotives built for the Great Northern and the Virginian Railways, and it is hoped that a companion paper of equal merit will be prepared covering the actual operating and maintenance experience of these locomotives over the period culminating in their first major overhaul.

CHARLES KERR, JR.⁷ In the heavy-grade territory served by the Great Northern and Virginian railroads, the type of power described in the paper should give a good account of itself.

The authors make a strong case for the advantages of low voltage direct-current traction motors. These advantages are not denied. However, it is thought that credit might be given to improvements being made in locomotives equipped with alternating-current traction motors. In this connection, the following comparison is given between the two motor-generator locomotives discussed in this paper and locomotives now under construction for the Pennsylvania, equipped with alternating-current traction motors:

	Great Northern	Virginian	Pennsylvania
Trolley voltage.....	11000	11000	11000
Frequency cycles.....	25	25	25
Maximum speed, mph....	65	50	65
Locomotive weight lb....	735000	1033832	540000
On drivers, lb.....	735000	1033832	540000
Continuous hp.....	5000	6800	5625
Maximum hp.....	5800	...	7500
Continuous tractive effort, lb.....	119000	162000	90000
Rated per 100 tons on drivers			
Continuous hp.....	1361	1361	2084
Maximum hp.....	1578	...	2777
Continuous tractive effort, lb.....	32370	31340	33330

For equal driver weights, the Pennsylvania locomotive with

alternating-current motors produces a maximum tractive effort equal to the MG type. At speeds, it produces greater horsepower for the same weight, making a more versatile locomotive for territories where both drag and high-speed service may be encountered.

Any railroad, using the alternating-current system, can be assured of excellent motive power with locomotives of the MG type, or with those using alternating-current traction motors.

T. M. C. MARTIN.⁸ Motor-generator locomotives are virtually without peer in western mountain-grade applications. Hence the writer is somewhat at a loss to understand the reasons why motor-generator locomotives are so greatly underrated by the motive-power fraternity. It would seem that they are deserving of much more attention and respect than they customarily receive. In spite of this paper, and its apparently enthusiastic support by equipment-manufacturing personnel, nevertheless, the impression exists that the motor-generator locomotive is not openly espoused with great joy by the builders. It is said to be the most expensive type to build. The writer is not in a position to say, but does believe there may be economic reasons to support a somewhat higher first cost.

The apparent recipient of the builders' most extravagant praise in recent years is the straight alternating-current series motor locomotive similar to the Pennsylvania's GG-1 class. Although it is freely admitted that, as originally conceived and built, the GG-1 could not fulfill the requirements of "laying-up" against the load in mountain-grade operations without benefit of armature rotation, as described in the paper, there seemingly is agreement that a locomotive of the series alternating-current type can be built that will equal the performance of the motor-generator type in this respect. There are rumors that such a locomotive is even now being erected.

Be all this as it may, and the writer does not wish to be recorded as a scoffer on the basis of the possible physical performance of a series alternating-current locomotive, it occurs to him that there would still be two or three characteristics peculiar to the motor-generator type that would clothe it with definite superiority over other electric locomotives.

Consider, for example, power factor. If it be assumed that a series alternating-current type locomotive would have an average operating power factor of about 0.8 lagging, it is evident that a unit of continuous output rating comparable to the Great Northern's 5018 class motor-generator type would have the approximate 5-4-3 right-triangle relationship of 5000 kva, 4000 kw, and 3000 rkva.

Even to approximate the Great Northern 5018 class, such a locomotive should be equipped with capacitors capable of supplying at least 3000 rkva. The placement of perhaps 1500 cu ft of capacitors, together with their control apparatus on the locomotive, might require some little ingenuity. It may be doubted that such a locomotive could be brought up to unity, much less leading power factor anywhere near as easily or economically as it is accomplished automatically in the motor-generator locomotive.

Next is the matter of regenerative braking. It is generally agreed that the motor-generator locomotive is the ideal type for regenerative braking. We may disregard the operating advantages of regenerative braking since the series alternating-current type could be provided with a dynamic brake that would be almost, if not quite, as good.

What cannot be brushed aside lightly is the economic waste involved in dissipating valuable electric energy unnecessarily in resistance grids when it might be returned to the line to serve

⁷ Consulting Transportation Engineer, Westinghouse Electric Corporation, East Pittsburgh, Pa. Mem. ASME.

⁸ Electrical Engineer, Bonneville Power Administration, United States Department of the Interior, Portland, Ore.

useful purposes elsewhere. Evidently most engineers do not appreciate fully the economic value of regeneration on western railroads, and the writer would like to develop this subject briefly with respect to Great Northern operations.

In terms of present utilization on the Great Northern, the 5018 class is able to approximate only 1.5 round trips or 225 miles per day. This is about 80,000 miles per year—not a particularly impressive figure. In freight service with about 2400 gross tons, including locomotive, this is equivalent to about 192,000 kgm⁹ per locomotive per year. On the present Great Northern electrified zone, the gross energy consumption (motoring) will be about 50 kwhr/kgm, the regeneration will be about 10 kwhr per kgm, making a net consumption of about 40 kwhr/kgm (all energy figures are as of 3-phase, 60 cycles supply points).

The value of regeneration then is about 1,920,000 kwhr per year, which, at the present rate schedules in effect on the Great Northern (fractionally in excess of 1.0 cent per kwhr) amounts to about \$20,000 per year per locomotive.

Lest this appear to be too special a case built around a relatively high proportion of heavy-grade operation, let us suppose that the Great Northern electrification is extended both ways from present termini until it includes the entire main line from Seattle to Spokane, some 330 route miles. In this event, individual locomotive mileage could quite easily be brought up to 500 per day or 180,000 miles per year. It is estimated that motoring and regenerative energy would approximate 32 kwhr and 4 kwhr per kgm, respectively. The locomotives would now be handling 2400×180 or 432,000 kgm per year. At 4 kwhr/kgm this would mean an annual total of 1,728,000 kwhr of regenerative energy, having a value of some \$18,000 per year at present Great Northern power rates.

The Great Northern examples cited are believed to be entirely typical. Most sections of western main line that are economically feasible of electrification have profiles embodying sufficient regeneration potentialities to warrant adoption of motor-generator-type locomotives for economic reasons alone. Even if present electric power rates are cut in half, it seems evident that not

⁹ kgm = thousands of gross-ton-miles.

less than \$10,000 can be saved per locomotive per year through utilization of regeneration. Couple this with the ability of the motor-generator locomotive to produce rather than use reactive power, and another 20 per cent saving can be claimed annually. The potential savings from these two factors would appear to run from \$12,000 to \$24,000 per locomotive per year, depending upon the basic rate schedules under which electric power is purchased. If money is assumed to be worth, for example, 6 per cent, this is equivalent to saying that a railroad can afford to expend from \$200,000 to \$400,000 more per locomotive for motor-generator locomotives even if it is believed there are no other reasons for preferring them. It wouldn't appear that they need to cost this much more per unit to build, and, as the authors have shown in this paper, there are many important reasons why motor-generator-type locomotives are superior.

It would appear to the writer that before a railroad purchases alternating-current series motor-type locomotives of clearly inferior characteristics as regards power factor and regeneration capabilities merely on the basis of lower initial cost, it should understand fully that it is probably going to be paying a very substantial premium in the form of higher operating costs. It can be demonstrated that in the case of most western railroads, the differential savings resulting from the operation of motor-generator locomotives will support a much higher initial cost for such locomotives should this be found to be really necessary.

J. STAIR, JR.¹⁰ For the profile and train movements encountered on the electrified sections of the Great Northern and Virginian Railways, the motor-generator type of locomotive appears to be well-adapted. The present paper covers the situation admirably.

It would add to the value of the paper, as a permanent record, if "speed-traction effort" and "speed-braking effort" curves were included for the latest class of electric locomotive on each of these railways.

¹⁰ Electrical Engineer, "The Pennsylvania Railroad," Philadelphia, Pa.

Two Slants on Postwar Wood Finishing

Part I—Current Practice

By P. S. KENNEDY,¹ NEWARK, N. J.

The postwar period has witnessed much activity and growing interest in the finishing of wood. This has been due to the following factors: (1) The ever-present objectives of greater speed and reduced cost. (2) The desire for better and more resistant finishes. (3) Increasing recognition that ultimate cost, rather than package cost, should be the yardstick of value for finishing products. (4) The vital need for a quick and consistent method for anticipating the check resistance of lacquer films, in particular. This trend has been accentuated by unusual circumstances. These aspects of current conditions in the wood industries are treated in this paper.

GREATER SPEED AND REDUCED COST

IN line with general experience, the postwar period has included a seller's market in the wood industries, together with radical increases in labor cost. Accordingly, aims have been to produce finished units rapidly, plus all possible economies.

Probably the sorest spot in wood-finishing materials is the filler which must be applied on open-grain woods such as mahogany, walnut, and the like, and intensive activity has been directed to a cure. In the prewar period, filler was generally regarded as a necessary evil, as well as a staple product to be purchased at a staple price, like flour or sugar. It was relatively slow drying—overnight being the usual minimum drying period—but in addition, subsequent performance was unpredictable—particularly with lacquer finishes. Various deviltries developed periodically, the most poignant of which were the so-called "graying of pores" and an unsightly "muddying"—usually in sections—of what should properly be a uniformly clear transparent-film effect.

One of the most constructive results of this postwar experience has been the growing appreciation by the consumer that the established practice of buying filler "at a price" could be short-sighted. When one of these epidemics of graying of pores, or muddying of films was encountered, the corrective labor expense invariably produced a staggering ultimate price tag. Sufficient consumers adopted this line of reasoning to encourage the finish manufacturer, for the first time, to spend time and money on the development of filler, with the assurance that a successful effort would receive a just return.

A receptive attitude was also created toward tolerance of change in long-standing shop practice for the handling and application of filler. For instance, a new filler development, because it had to be handled faster, might require two men to wipe off a large unit, rather than one man. Actual man-hours would be the same, however. Again, a new filler development might not suspend as well after reducing for use, and thus require an occasional stirring which would not have been necessary with the older type.

¹ Vice-President, Finishes Division, Interchemical Corporation. Mem. ASME.

Contributed by the Wood Industries Division and presented at the Wood Industries Division Meeting, Jamestown, N. Y., September 27, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49—WDI-2.

Thus fillers have come into use, employing various synthetic vehicles, as contrasted with the long-accepted linseed-oil vehicle, and drying time, not only shortened to periods such as an hour, but also giving better clarity, which is another way of saying "proof against pore graying and muddled films." The ultimate in this direction has been achieved with the stain-filler combinations, employing fast-to-light dyes. The best of these products not only give "tops" in clarity; but they are absolute proof against pore graying. The explanation for this is that the translucent inert pigments, used in the filler, are themselves actually dyed. They therefore do not "dry out" or "wash out" to an unsightly pore condition.

Particularly in fast production, such as radio cabinets, operators, who have been open-minded in adjusting labor practice to conform with the product, have been able to effect important economies by the elimination of both material and labor costs. For example, a good-quality finish, employing stain and filler separately, first calls for the material and operation of applying a coat of stain. Next, a sealer wash coat of either lacquer or shellac of low solids content, followed by a scuff-sanding operation. The purpose of this is to seal the pores so that when the filler is subsequently applied some of its vehicle is not sucked away by stray capillaries in the wood, robbing the full strength of the filler, as well as giving "smeary" pore effects at such points.

With a stain-filler combination, all of this is combined into a single operation with a single product. But while, from this point on, the application of the top coats would be identical, the danger of graying still exists with the simple filler. Sometimes precaution is taken against this by formulating so that the filler is tinted with so-called oil-soluble anilines. When the top-coat material is applied, these anilines "bleed" and in so doing stain the inert pigment. The objection to this is that it is a temporary measure, as these colors are not fast to light and may subsequently provide embarrassment. Another method of obviating against graying is the application of a shading stain over all. While this tends to color over potential gray pores, it is at some sacrifice of finish clarity, plus being an additional operation.

In all frankness, it must be admitted that these so-called fast fillers and stain-filler combinations, are not as foolproof as the old-fashioned filler for wiping and cleaning up; nor for packing the pores quite as full. But the good ones do a most acceptable job, as the mechanic gets the hang of them. Supplemented by the continuing laboratory work of the maker, further improvements and refinements are being progressively achieved.

The best of these synthetic types of fillers do not "heave" like the old-fashioned filler. This is temporary "lifting" from the pores, which occurs when top-coat material is freshly applied, and gives the illusion of a most flushy filled job. Unfortunately, there is a subsequent collapsing which shows up as "shrinkage." The best of synthetic fillers frequently look "hungry" by comparison because they are not so affected by freshly applied top coat, with the pore filling remaining fixed. With the continued support and co-operation of the user, the future outlook for filler is most promising.

Another angle of reduced cost applies most specifically to lacquer jobs. From the standpoint of speed, saving of floor space,

and fast and easy touch-up and repair, lacquer is the ideal finish for wood. But it does have the shortcoming of what might be termed low solids or film thickness.

There is a definite limit to the amount of solids which can be incorporated in lacquer and still maintain a suitable spraying viscosity. Roughly speaking, varnish will have twice the solids or double the film thickness of a lacquer coat. Much work has recently been done to improve this deficiency in lacquer, and along two lines; one by increasing the solids content of the lacquer, and the other, by hot-spray application. While both of these measures have proved effective, from the standpoint of giving possibly a 50 per cent increase in film thickness over what is regarded as normal (a 21 per cent lacquer) sufficient resistance and objection have developed to prevent general adoption.

A resultant trend has been to secure the desired film thickness by means of synthetic coatings—of which alkyd-urea base compositions would be typical—and these are currently finding some usage. The cure of these coatings is activated by means of a catalyst, and while some are available in air dry form, most of them require stimulation by heat. The average temperature ranges employed are between 130 and 135 F, as there is a pronounced feeling that in exceeding that maximum temperature vagaries of wood and glue are apt to cause complications. However, on some current government furniture work, specifications call for 150 F.

Best and surest satisfaction is secured by adding the catalyst to the coating just prior to the time of use; although some of the products are supplied with catalyst added. In this connection, there is always a question of package stability, and potential difficulty exists if the user does not have a rigidly enforced system of first using up the oldest finishing material on hand.

Investigation by finishing manufacturers is currently under way with various kinds of synthetics, and further developments can be confidently expected with synthetic clear coatings.

BETTER AND MORE RESISTANT FINISHES

The advent of the synthetic finishes, besides affording savings because of heavier film thickness, introduces varying degrees of resistance, which are highly interesting from the sales and service angle. When cured, many of them have outstanding resistance to alcohol and many other materials which affect lacquer and ordinary varnish films.

The maximum properties in these finishes are secured when the work is top-coated entirely with these coatings. But for various shop reasons there is quite a general trend toward using an undercoat of lacquer-type sealer, followed by a top coat of the synthetic. Importantly involved in this is the economy in sanding and the avoidance of possible "shelving" of coats of the synthetic

itself when the cure of the undercoat has been carried too far to permit of proper knitting between the coats.

Here again, however, this is a matter amenable to ready control in a well-regulated finishing room, because it is possible to get satisfactory sanding on undercoats of synthetic, and to provide against too complete curing of undercoats.

ULTIMATE COST VERSUS PACKAGE COST

There has been a decided and significant increase in the application of accounting practice in wood-finishing departments to more careful and detailed segregation of costs. In these instances the package or container cost of finishing products is no longer the prime consideration, and many revealing instances have occurred as the result of teamwork between the purchasing agent and the finishing superintendent.

Actual mileage is not necessarily the most important factor. Hospitalization—or touch-up and repair—is frequently the most potent figure. Accessories, such as sandpaper, cost real money these days, but are too often taken for granted, rather than investigated from the angle of whether much less would be used with another finishing product. Savings in sanding, rubbing, and polishing time all add up to the careful scrutiny which is being given, more and more, and the net importance of which cannot be over-emphasized.

QUICK METHOD OF TESTING LACQUER FILMS

The rugged winter of 1947-1948 not only accentuated the need of a greater margin of safety for lacquer films, but for a quick method of evaluating them. To be factual, the blame for the widespread finish failures should not be laid entirely to the finishing materials—specifically lacquer. Because of rush and shortages, much lumber and veneer were used, which were not in normal condition, to say the least, and the stresses and strains which they created placed an undue load upon the lacquer coats.

However, it emphasized a fundamental deficiency in formulations to meet abnormal conditions—not only weather like 1947-1948, but changes in merchandising conditions. Typical of these would be warehousing of finished products, which will increase importantly. It is well known that ordinary lacquer films lose check resistance on standing; so there is the double problem of pronounced improvement in lacquer films, and a practical method of measuring their strength.

The present accepted methods for so-called "cold check" are not only time-consuming and expensive, but undesirably open for error. Hence a radical correction of this situation would be of such dynamic importance that the companion paper which follows as Part 2 warrants thorough consideration.

Two Slants on Postwar Wood Finishing

Part II—Suggested Method for Predicting Check Resistance of Lacquer Films

By W. T. SMITH,¹ NEWARK, N. J.

This paper presents details of equipment and technique for performing control tests on film-forming materials. Typical tests are interpreted and correlated, and illustrated examples are given of test results on various lacquers.

THE tendency of clear, lacquer-type furniture finishes to fail by severe checking or cracking, especially under exposure to wide and abrupt changes in temperature, has long resisted accurate and significant laboratory prediction and control. In an effort to perform control tests of the film-forming media, carefully controlled and presumably representative wood panels are prepared, aged for a period of up to 2 weeks and then subjected to a systematic cycle of temperature extremes in an effort to establish the limits of check resistance of the finishing system in question.

Distinct stresses are set up in a cellulosic film in the process of setting. This effect is influenced by the nature of the incorporated resin as pertains to solvent release and basic molecular arrangement, the viscosity of the cellulose, and the thickness of the film. The actual moisture content of the film itself, especially in the presence of alkyd resins and/or vegetable oils, is a directly pertinent influence on tendencies to check at low temperatures. It is indicated by Koenig² that mechanical failures such as checking and cracking are rupture phenomena, and the result of external and/or internal forces. These phenomena are influenced by non-uniformity of the film or the substratum which leads to local stresses.

Checking of lacquer films is due to three factors, as follows:

- 1 The deforming force.
- 2 Nonuniformity of the film.
- 3 Local stresses exceeding the film strength.

Deforming forces may be caused by changes in the substrate. Moreover, the film may undergo contraction on aging, and this may lead to stresses and strains in the film which are dependent upon the mechanical properties of the coating. The solvent will evaporate from the lower layers much more slowly than from the outer layers. Consequently, the stresses in the outer layer will grow more rapidly than in the lower layers, reach a maximum value in the surface layer, and decrease in the direction of the substrate. However, as the drying and aging proceed, the distribution of stresses will become more uniform. Shrinkage takes place at a measurable rate for a period of 30 days or more and, together with progressive development and relief of stresses, is not confined to a short time interval. When films dry and age,

shrinkage occurs, which results in deformation and causes stresses. The theoretical examination of the mechanical processes taking place during film formation indicates that stresses occur even while the film dries.

WOOD-PANEL TESTS

Variation has long been a persistent attending factor in the performance of wood-panel tests for cold-checking tendencies of lacquer systems. In an effort to identify the variables influencing the result of wood-panel tests, an evaluation of a representative furniture-finishing system was made by finishing large plywood specimens and cutting them later into smaller test pieces in an attempt to minimize wood source variations. The tests were performed on specification panel stock, especially constructed and furnished for test purposes. This panel stock consists of a $\frac{3}{16}$ -in. yellow-poplar core, $\frac{1}{32}$ or $\frac{1}{16}$ -in. yellow-poplar cross-banding, and face and back of mahogany and sap gum, respectively, of about $\frac{1}{32}$ in. to make up a $\frac{3}{16}$ -in. resin-bonded panel.

The lacquer system involved is of the conventional radio-cabinet type, consisting of the following:

- 1 Non-grain-raising stain.
- 2 A light cellulosic wash coat.
- 3 A paste filler.
- 4 A 20 per cent nonvolatile sanding sealer.
- 5 Two coats of a 21 per cent clear rubbing-type finishing lacquer.

This single representative system was used in all tests described herein.

The cold-check cycle referred to consists of the conventional 1 hr at 120 F, followed immediately by 1 hr at -5 F to complete each cycle. Inspection is made at an oblique angle in strong light after each cold period.

CONCLUSIONS

1 The major and basic conclusion evident here is that wood-panel tests for cold-check tendencies in any normal scope of handling and condition are rampantly inconsistent.

2 The moisture content of the wood at time of finishing, especially within the range of conventional precision woodworking practice, is not a significant factor to a consistent degree.

3 Moisture sealing of the wood member on all unfinished surfaces has the effect of causing a slight increase in resistance value in isolated sections, but causes a somewhat wider spread of results to the end of increasing the inconsistency of the test results.

4 Moisture conditioning of the finished member by storage in varying conditions of relative humidity is the most influential factor observed here. Variation of moisture content of the finished member—wood and finish—from 5 to 10 per cent moisture content, will effect a variation in check resistance of from 500 to 800 per cent.

5 While the combined precautions of moisture conditioning and moisture sealing will, in a majority of cases, prove slightly

better than moisture sealing alone, this result is not completely consistent.

6 Checking results cannot be assigned to any continuity or relationship of wood structure, even in adjacent sections of the same original stock.

7 It must be concluded that wide variation in results on wood test panels may be expected from unpredictable, natural variations in wood density, structure, and composition, over and above the demonstrated sensitivity to handling and ambient condition, to the extent that it is not practical or feasible to evaluate the checking tendencies of an organic-finish film conclusively by this method.

FILM TESTS ON A METAL SUBSTRATE

The most exhaustive study of cold-check evaluation on the media of wood surfaces will serve mainly to emphasize the number and complexity of variables present, or potential, in a wood substrate. Such are these variables and vagaries of behavior that they cannot all be measured, classified, or even recognized. In setting out to evaluate the unknown checking potential behavior of a finish film on a wood surface, we are employing an unknown element over a substrate of a similarly unknown and unpredictable nature. In order to permit equitable measurement of a potential value in a material of unknown behavior, an accompanying medium of known and controllable properties is indispensable. Constructive thinking in various fields has led experimenters toward the employment of such constants.

C. W. Smith³ states that stress lacquers have long been used as a surface indicator to show, by induced checking, the presence of stress lines in the body of the substrate under scrutiny. Stress lacquers are specially formulated brittle materials of a known and controlled behavior as pertains to tolerance of lateral stresses. Castings and similar metal parts are coated to a thickness of from 0.0003 to 0.0008 in. with these lacquers and subjected to heavy operational stress and strain in suitable testing apparatus. By the nature and direction of the resulting fracture lines in the brittle coating, the stress reaction of the substrate in question may be observed and evaluated.

Since checking failure of wood finishes is the result of an inability of the surface coating to cope with dimensional changes in the substrate, it would seem to follow that systematic controlled manipulation of an amenable substrate would permit the assignment of a specific resistance to the finish film under scrutiny.

Attempted manipulation of the substrate is the principle involved in conventional wood-panel checking tests, but the direction and extent of the induced dimensional change cannot be controlled or predicted in other than very general terms.

An applicable substrate may be found in the form of very thin sheet copper of known and specified temper and ductility. When such a surface is coated with the film under test, the sheet and the film together may be deformed systematically under hydraulic pressure to form a "dimple" or hemispherical section, the surface area of which represents a measurable increase or distention of its original dimensions.

If the film is cured to a constant state, the distention performed at controlled low temperature and the distention on the radius of the spherical section measured to 0.0001 in., the actual substrate expansion at the point of fracture failure of the film may be expressed to an accuracy of 0.1 per cent.

Small⁴ states that film flexibility, as evidenced by cold-check failure, may be correlated with elongation data, and that there is a

striking correlation between cold-check resistance and the degree of elongation. Comparison of values so obtained on standardized formulations, on which cold-check data from wood-panel tests, as well as from field applications, have been accumulated over a period of years, serves to correlate results of the distention method with those obtained on wood surfaces. Such comparisons also serve to indicate the limits of movement of conventional wood surfaces in terms of per cent of area increase and lead to the conclusion that finish failures on wood surfaces are avoided by maintaining a standard of distention potential, at low temperature, at a level offering a margin of safety over the range covered by the behavior of wood.

In so calibrating the "distention-potential test," a series of thirty materials was used, the relative cold-check resistances of which, in terms of hot and cold cycles, have been well established. The distention potentials of these materials fall, Table 1, into well-defined groups or fields which have been designated arbitrarily as Classes I to IV inclusive. The accuracy of the distention factor as a criterion of checking potential has been found to be such that a specific formulation will not fall out of class unless there has been error in compounding. Repetition of tests of the same lot of material show an operational aberration in result of between 5 and 10 per cent only.

TABLE 1 CLASSIFICATION OF 30 REPRESENTATIVE LACQUER FORMULAS BY DISTENTION-POTENTIAL TEST

	Class IV	Class III	Class II	Class I
Tolerated distention	Not over 0.0700	0.0700 to 0.0850	0.0850 to 0.1000	Over 0.1000
Per cent increase in area	Not over 1.4 per cent	1.4 to 2.3 per cent	2.3 to 2.8 per cent	Over 2.8 per cent
Considered	Poor	Fairly good	Good	Excellent
Approximate Wood cycles—	3 or less	8 to 10	15 to 18	Infinite number
<i>Sealers</i>				
Under 21 per cent.....				4
21 to 25 per cent.....	1	3		
Over 25 per cent.....	2			
<i>Lacquers</i>				
21 per cent solids.....	8	5, 6, 7, 17, 18	21, 22, 23	9, 10, 11, 12, 13, 28
25 per cent solids.....	16		24, 25, 26, 29	
28 to 30 per cent.....	14	19, 30, 20*	27	15

Routine control methods of this test are such that by use of a standardized substrate and controlled coating and curing methods it is possible to make an accurate cold-checking evaluation within an elapsed time of 24 hours after the sample is received in the laboratory.

PREPARATION OF SPECIMENS

Choice of coating methods of the copper specimens is limited by the flimsy and flexible nature of the thin sheet which is 0.0050 in. \pm 0.0004 in. The most convenient and practicable method of coating was found to be by controlled pour or flowdown. A 7-in. length of the 6-in. strip is affixed by masking tape, extending $\frac{1}{4}$ in. over the sides, to a stand or easel at 50 deg from the horizontal. Since two separate flowdowns are made on each such specimen plate, $\frac{1}{8}$ -in. tape may be applied vertically to the center of the panel as a separator. One fluid ounce of the lacquer under test is brought to 25 \pm 1 deg C and flowed down over the 2 \times 7-in. area, pouring as closely as possible to the top edge and completing the pour in four rapid passes across the 2-in. space. If the surplus is recovered as it flows from the lower edge, it will be found that about 24 ml will be recovered, requiring a consumption of about 6 ml or $\frac{1}{4}$ fluid oz (approximately) for the test film.

Consideration or control of viscosity or nonvolatile content of the materials under test is not made at the time of coating these specimens. Since most furniture-type lacquers are supplied ready for use, it is presumed that the material under test is of

³ "Brittle Lacquer Stress Analyzers," by C. W. Smith, *Paint Incorporating Paint Manufacture*, vol. 17, October, 1947, pp. 333-335.

⁴ "Improvements Derived From Using Resins Designed Specifically for Lacquers," by J. O. Small, *Official Digest*, Federation of Paint and Varnish Production Clubs, no. 288, January, 1949, pp. 23-35.

viscosity and solid content amenable to normal spray application. Experimentation therefore has been based upon lacquers ranging naturally from 21 per cent to 30 per cent nonvolatile, and in viscosity from 45 sec to 70 sec, ASTM No. 7 Cup, as a representative coverage for clear cellulosic materials at spraying consistency. Since distention is made of each pour at three stations for an average result, the thickness of film deposited at the respective stations has been observed and considered carefully. Station A is at 1½ in. from the top of the pour, Station B at 3½ in., and Station C at 5½ in., respectively.

Film thickness of the pour, for lacquers at spraying consistency, will be found to range from 0.0005 to 0.0007 in. at Station A, according to viscosity and nonvolatile content and to increase about 0.0002 in. at each subsequent station. Such is the secondary influence of the viscosity and nonvolatile factors that their influence on film thickness may be ignored in the process of achieving a distention-potential value of cellulosic materials at spraying consistency.

Application of the distorting pressure is made in a modification of the familiar Mullen tester used for paper testing, and which is modified to a distention apparatus by the addition of a 0.0001-in. dial gage, mounted with the plunger contacting the center of the operating area for the purpose of measuring the spherical radius of the distention.⁵

CURING THE FILM

The cure of films for the significant evaluation of distention potential must be constant for a dual purpose: to bring the films to a constant condition as pertains to solvent content, and to insure a consistent condition of moisture in the film. It has been found that films of this thickness on a copper substrate may be brought to a very satisfactory constant condition by curing for 16 hr at 120 F in a forced-draft convection oven. This forcing period may be applied at any time after 15 min following application of the films, up to 8 hr.

TEMPERATURE AT TIME OF TEST

Actual performance of the distention operation at room temperature was found to result in a certain instability and inaccuracy of result. While the actual degree of error prevailing is not significantly great, it is found that the numerical value of the distention factor obtained is approximately proportional in direct ratio

FIG. 1 EFFECT OF TEMPERATURE AT TIME OF DISTENSION ON FOUR REPRESENTATIVE LACQUER FILMS

to the temperature of the film and substrate at the moment of drawing, Fig. 1.

The process of arriving at the correct temperature for testing, where a machine based on the Model C Mullen tester is cooled by placing it within a refrigerator, is shown in Fig. 2. It will be

⁵ U. S. Patent no. 2,332,818.

FIG. 2 PROGRESSIVE COOLING OF HYDRAULIC FLUID OF DISTENTION MACHINE WHEN PLACED IN A REFRIGERATOR AT -20 C

FIG. 3 RATIO OF DISTENSION OF FILM IN 0.0001 IN. ON RADIUS OF SPHERICAL DISTENSION TO ACTUAL INCREASE IN AREA IN PER CENT

noted that the hydraulic fluid of the machine will have reached a temperature of about -3 C (26.6 F) in 1 hour, a point generally satisfactory for making check evaluation distentions.

PERFORMANCE OF TEST

Specimens are removed directly from the oven for placement in the distention machine for testing. Reduced as the films are by the 16 hr of elevated temperature curing to a minimum constant as pertains to moisture content, the film will absorb atmospheric moisture rapidly after removal from the oven. Since the checking potential of many films is affected by moisture content, it is important that this factor be maintained constant.

Under a concentrated light, such as from a microscope illuminator, directed obliquely on the exposed circular area within the clamp of the machine, the incidence of failure of the film by abrupt fracture is positive and instantaneous and readily observed. The possible variation of rate of application of pressure is not great, though turning of the compressing screw at a constant speed is advisable. The motor-driven machine operates at 120 rpm. On observation of fracture failure, the pressure increment is stopped at once, and the vertical distention at the center of the spherical distortion is read to 0.0001 in. accuracy. Expression of the distention-potential factor in per cent of expansion of the area involved is plotted in Fig. 3. The per cent increase of the circular area distended into a spherical segment is calculated by the formula

$$P = \frac{100D^2}{R^2}$$

where

D = vertical distention as read from dial gage of distention machine

R = radius of distended area, or 0.59375 in.

Stations A, B, and C, representing progressive distances from the top of the flowdown as previously described, are run successively, and the results in 0.0001 in. are averaged for the expressed value for the material under test.

INFLUENCE OF FILM THICKNESS ON CHECKING TENDENCY

While it has been customary to assume in both tests and practice that, all else being equal, checking hazard increases more or less in proportion to film thickness, viz., that a heavy film is immediately more conducive to checking failure, experience in reading distention potentials and, ergo, the tendency of the film to exhibit failure by checking, serves to indicate that this ratio is not a true proportionate one. Koenig² indicates that the rate and extent of the development of stresses in a cellulosic film drying by evaporation of solvent, is influenced not only by the thickness of the film, but by the rate of evaporation, viz., the nature of the solvents and the ambient condition of the atmosphere, the solvent-retention properties of the nonvolatile constituents, and the aging factor of the stress development. While it cannot be denied that film thickness is a factor in checking propensity, the number of variables present is such that prognostications of proportionate influence cannot be made with impunity.

Examinations made of films ranging from 0.0005 in. to 0.0050 in. thickness by the distention-potential method show relatively little proportionate effect due to the fact that a standard procedure of curing the films for test will not develop in all thicknesses of film the same degree of stress. The greater mass of the heaviest films is prevented from early failure by the presence of unreleased solvent and the incomplete development of stresses. The very fact that the release of solvent is more gradual, in itself, affects the final extent, direction, and nature of the end stresses developed. The exact extent and behavior of the end stresses developed in any one application and of any one formulation of film-forming material defying comprehensive regimentation, it does not seem possible to formulate a rule for the exact effect of film thickness on checking tendency.

The normal effect of film thickness on the distention-potential test for one representative low-potential material is shown in Fig. 4. An increase here of slightly over 100 per cent in film thickness—from 0.0007 in. to 0.0015 in.—serves to reduce the distention potential about 200 points, causing its classification to descend from Class III into Class IV. The actual differential represented would probably amount to from 3 to 5 cycles of panel

FIG. 4 EFFECT OF 100 PER CENT INCREASE OF THICKNESS OF TEST FILM OF CONVENTIONAL CLASS III LACQUER

checking value. This material is a sealer, and since the curve enters Class IV at a film thickness of slightly over 0.0010 in., it is considered a Class III material with a normal checking potential of 8 to 10 cycles.

Film thickness of ready-to-spray lacquers may be disregarded in this test since the film deposited by the temperature and angle of incident flowdown is in itself a characteristic of the individual material. The natural flow and "hang" of the material, as affected by viscosity, rate of solvent release, and nonvolatile content, will induce a similar corresponding effect in commercial application. Thus a material which, as offered at spraying consistency, deposits a film of certain thickness having a distention potential of a specific value for this normally deposited film of the material, may be assigned a significant evaluation of its potential behavior in commercial use.

Commercial application of course connotes a heavier film than is used in the laboratory distention evaluation. It is possible, however, by correlation of these results with field experience to assign a relative value to the behavior of uniformly cured films which is an equitably accurate criterion of their ultimate behavior in field use.

INTERPRETATION AND CORRELATION OF RESULTS

Values in checking potential which are assigned, therefore, through the Class I to Class IV evaluation just described, are so adjusted as to connote a prediction of the behavior of the material in question in conventional practice.

All coating materials are evaluated singly whether designed and used as an undercoat or as a finishing coat. Such materials are usually formulated for reciprocal association and, as such, will be found to fall into a similar bracket of distention potential. In this case the resulting distention value is considered the value for the complete system, consisting usually of an undercoating and two finishing coats.

Where a wide divergence of value between under and finishing elements is obtained, it is indicated that the finishing coat is the dominant factor in checking. Not only is a greater amount of this material applied in the double coat in conventional use, but by being superimposed in the system and exposed to the air, earlier development of complete stress is realized. If the undercoat exhibits a lower distention potential, its effect will be much delayed by the slower development of stresses due to its submergence in the system. Further, the undercoat, lying adjacent to the insulating substrate formed by wood, is never subjected to as abrupt thermal shock as is the surface coating.

Adequately accurate predictions of the potential checking resistance of furniture-type finishing systems may be made by assigning a value to the system, based upon the proportionate application of the respective materials in question. Thus if an undercoat and finishing coat fall into the same distention potential class, that value may be accepted as the value for the system. Unless the distention potential of the undercoat is two or more classes below that of the finishing coat, the value of the finishing coat may be accepted for the entire system in practically all cases. Where the differential between materials is several classes, the aggregate point for the system will fall a point between the extremes proportionate to the number of applications of each respective material. For example, in case of a wide divergence in undercoat and top coat to be used as a single and double coat, respectively, the potential checking-point value will be approximately one third of the differential between the individual values below the greater.

It may be that the underlying causes of cold checking, especially as pertain to basic formulation characteristics, have not been understood completely. Sanding sealers, for example, are generally considered to be "short" materials as a concession to their incorporated sanding property. The issue, however, is confused in a measure by the fact that not all the factors conducive to production of a "short film," are contributors to early cold-checking tendency. The use, for example, of metallic soaps as sanding

agents does not contribute largely to checking tendency, nor does the amount of added plasticizing agent or the rate of solvent release. The principal offender in cold-check failure is the hard resin. Softness or "cheesiness" of a sealer film, or even some degree of brittleness, as evinced by some such test as a mandrel bend, do not necessarily connote low cold-check resistance. Decrease or omission of plasticizer in a typical furniture-lacquer formulation will be reflected in the distention potential, and in a manner which reveals that the effect of plasticity so induced is not proportionate but takes the form of a logarithmic curve.

In Fig. 5, material (A), a high-grade piano lacquer, falls from its normal position as a Class I material at a distention factor of 0.1153 to Class III, distention factor 0.0833 with the omission of 25 per cent of the normal plasticizer. It remains thereafter in Class III even when plasticizer is omitted completely. Material

FIG. 5 EFFECT OF PLASTICIZER CONTENT ON DISTENTION OF A HIGH-POTENTIAL PIANO LACQUER (UPPER CURVE) AND A CLASS II RADIO-CABINET MATERIAL

FIG. 6 LACK OF RELATIONSHIP BETWEEN DISTENTION POTENTIAL (SOLID LINE) AND SWARD HARDNESS (BROKEN LINE) OF CELLULOSIC SOLUTION WITH 23 DIFFERENT PLASTICIZERS

(B), a conventional furniture rubbing lacquer, has, as shown, a normal distention potential of approximately 0.0800. Elimination of 37.5 per cent of the plasticizer causes the rating to fall into Class IV, where it remains throughout the progressive elimination of the remainder of the plasticizer. The addition of extra plasticizer, to the extent of overplasticizing the material by 20 per cent, serves to raise the distention potential of the material into Class I at sacrifice of course of other such essential properties as resistance to printing and shrinkage.

Significant development of high distention potential does not occur until the maximum permissible plasticity (as gaged by other pertinent factors) is approached or exceeded. Varying amounts of plasticizer will not affect the distention potential of a film in the

same ratio as they will a mandrel bend or similar flexing or bend test.

That distensibility is a distinct property of the film is shown clearly in Fig. 6. Here a standard cellulose-resin solution was treated with 23 different plasticizers. Distentions were made, and the results plotted in ascending order. Sward hardnesses of the films drawn on plate glass by doctor blade are plotted in superimposed position over the distentions. The obvious absence of relationship in these properties needs no comment.

Fig. 7 shows equipment for distention of test sheets. Fig. 8 shows a typical test plate. Two pours, or flowdowns are shown, each with its respective three test stations. This is a lacquer of very high distention potential showing no failure here with all stations drawn to approximately 0.1840 in. in a vertical direction.

Fig. 9 shows a typical failure in a high-grade piano lacquer. The film thickness here is 0.0011 in., and the recorded distention potential, 0.1080, making this a Class I material which might be expected to resist efforts to check it on wood panels for an almost infinite number of cycles.

Fig. 10 shows the same piano lacquer having the distention test run on a heavy film of 0.0023 in. thickness. The "veined leaf" pattern is typical of the failure obtained from a thick film of high-potential material. The distention potential obtained here is 0.0963, showing that the excessive film causes a recession of value to the extent of one class only.

Figs. 11 and 12 are typical extreme fractures obtained from very brittle materials of low checking potential. The concentric fracture and glasslike shattering are typical. Fig. 11 is a clear furniture lacquer showing a distention potential of 0.0648. This is a Class IV material which would not be expected to exceed 3 cycles of panel testing. Fig. 12 of the same basic formula is a low-potential batch failing at 0.0567. Note the glasslike shattering combined with concentric fracture rings.

Effect of Fuel-Immersion on Laminated Plastics

By W. A. CROUSE,¹ MARGIE CARICKHOFF,² AND MARGARET A. FISHER²

The effects of cyclic and of continuous immersion in heptane, toluene, and SR-6, a test fuel, on the weight, dimensions, and flexural properties of nineteen samples of laminated plastics are reported. No one sample exhibited smaller changes than all other samples in all properties for all fuels, and for both cyclic and continuous immersion. The best weight and dimensional stability in the cyclic test was shown by a glass-fabric unsaturated-polyester laminate. The changes in flexural strength as well as in modulus of elasticity were losses in the majority of cases after the cyclic- and the continuous-immersion test. The unsaturated-polyester laminates varied widely among themselves in regard to the magnitude of the changes in a given property after an immersion test.

INTRODUCTION

INFORMATION regarding the effects of immersion in various fuels on the properties of laminated plastics is needed to evaluate these materials for use on aircraft, and to prepare specifications for such materials as are found suitable for this purpose.

This paper presents the results of tests made to determine the effects of cyclic and continuous immersion in three fuels on the weight, dimensions, and flexural properties of nineteen representative laminated plastic materials. The cyclic-immersion test involved alternate 24-hr periods of fuel-immersion and air-drying. The continuous-immersion test involved immersion in the fuels for different periods of time between 7 and 360 days. Both types of test were carried out at only one temperature, 77 F.

In view of the variability in properties to which the materials herein examined are usually subject, no attempt has been made to draw general inferences regarding the superiority of one or more of these materials relative to the others.

This investigation, conducted at the National Bureau of Standards, was sponsored by and conducted with the financial assistance of the National Advisory Committee for Aeronautics.

MATERIALS AND FUELS

The materials used in this investigation included commercial grades such as Grade C, L, and AA phenolic laminates, and several experimental materials of interest for aircraft application. The experimental samples were as follows: A number of unsaturated-polyester resin laminates reinforced with glass and cotton fabrics, a cotton-fabric melamine-resin laminate, a high-strength-paper phenolic laminate, a rayon-fabric phenolic laminate, two experimental phenolic laminates made with high pressure and low pressure, respectively, using the same Grade C cotton fabric as filler, and a paper-base lignin laminate.

The materials are described in detail in Table 1. They were obtained in the form of sheets approximately $\frac{1}{8}$ in. thick.

The fuels used were heptane (an aliphatic hydrocarbon), toluene (an aromatic hydrocarbon), and SR-6, a representative aircraft test fuel (a blend of aliphatic and aromatic hydrocarbons). The heptane used was a commercial *n*-heptane and the toluene, a technical toluene, both supplied by the Phillips Petroleum Company. The SR-6 used was a mixture of di-isobutylene (60 per cent), toluene (20 per cent), xylene (15 per cent), and benzene (5 per cent), and 0.2 lb of aviation-gasoline inhibitor per 1000 gal, supplied by the Standard Oil Company of New Jersey. The inhibitor consists of 50 per cent of *n*-butyl-*p*-aminophenol, 30 per cent of isopropyl alcohol, and 20 per cent of anhydrous methanol, and is added in order to hinder the oxidation of the di-isobutylene, a diolefin, with consequent gum formation.

TEST PROCEDURES

Specimens. The dimensions of the test specimens were 1 in. \times 3 in. \times the thickness of the sheet. The specimens were machined on a surface grinder with tap water as a coolant. The length and width were kept to within ± 0.005 in. of the given dimensions. One surface of each sheet was arbitrarily designated as the reference surface. The specimens of the cloth laminates were cut so that the direction with the greater number of threads per inch in the reference surface was lengthwise. As all the paper laminates were crossed-ply materials, the lengthwise direction of these specimens was arbitrarily taken parallel to one edge. The weight of the specimens varied from approximately 7 to 12 grams.

The specimens which were to be immersed were conditioned for 48 hr at 77 F and 50 per cent relative humidity (RH) prior to starting the tests.

Weight and Dimensions. The weight was determined to the nearest milligram. The length was measured to the nearest 0.001 in., and the width and thickness to the nearest 0.0001 in. The length was measured at two places, and the width and thickness at three places. The changes in weight and dimensions were determined with two specimens of each material. The changes in the length and width columns presented in the tables were determined by taking the mean of the average length changes and the average width changes.

Flexural Properties. The flexural tests were made in accordance with method No. 1031 of Federal Specification L-P-406a,³ using the 1200-lb scale of the 2400-lb-capacity hydraulic testing machine shown in Fig. 1. The flexural apparatus, Fig. 2, has been described.⁴ Load-deflection graphs were obtained in each test on a Southwark-Templin autographic recorder, which was operated by a Southwark-Peters plastics extensometer.

The 1 \times 3-in. specimens, which were immersed in the various test fuels, were cut into two 1 \times 1.5-in. specimens for the

A. Average for all specimens tested.

FIG. 1 HYDRAULIC TESTING MACHINE

FIG. 2 FLEXURAL APPARATUS

flexural tests. Because the test specimens were too short, a span-depth ratio of 8:1 was used instead of 16:1, as prescribed by Federal Specification L-P-406a. The reference surface of the specimen was on the tension side during the test. The radius of the support and pressure pieces was $1/32$ in. The relative rate of head motion was 0.01 ipm.

The flexural strength and the flexural modulus of elasticity were calculated in accordance with the equations given in method No. J031 of Federal Specification L-P-406a. The flexural-strength values reported are considered to be accurate to 1 per cent, and the flexural modulus of elasticity values to 3 per cent. All the values for the flexural properties are the averages obtained with four specimens except the initial values, which are the averages for six specimens.

The initial values for the flexural properties were determined on specimens which were heated in a circulating-air oven at 122 F for 48 hr and then conditioned for 48 hr at 77 F and 50 per cent RH prior to test. The changes in the flexural strength and the flexural modulus of elasticity as a result of immersion in the various fuels were calculated from these initial values.

Cyclic and Continuous Fuel-Immersion Tests. Each cycle of the cyclic fuel-immersion test consists of a 24-hr immersion and a 24-hr drying period. The specimens were immersed individually in 200 ml of test fuel in closed glass containers. Weight and dimensional measurements and flexural tests were made after 10 cycles of test and reconditioning at 77 F and 50 per cent RH for 48 hr.

The continuous fuel-immersion test consists of 7, 30, 90, 180, and 360 days of immersion. The specimens were immersed individually in 200 ml of test fuel in closed glass containers. Weight and dimensional measurements and flexural tests were made immediately after removing the specimens from the fuel on one set of specimens, and after reconditioning for 7 days at 77 F and 50 per cent RH on a second set.

^b Based on average value for two specimens.

RESULTS AND DISCUSSION

Weight and Dimensional Changes. The changes in weight, length, width, and thickness of the laminates immersed in heptane, toluene, and SR-6 are shown in Table 2 for cyclic fuel immersion, and in Tables 3 to 5, and Figs. 3 to 5, inclusive, for continuous fuel immersion. The samples having changes greater than ± 1 per cent for weight, ± 0.1 per cent for length and width, and ± 0.5 per cent for thickness in the cyclic fuel-immersion test and after 360 days of continuous fuel immersion are shown in Table 9. The data for the low-pressure Grade C phenolic laminate V were not included in the tables and in the discussion because of its great variability, but are shown in Figs. 3 to 5.

(a) **Cyclic Fuel-Immersion Test.** In the cyclic fuel-immersion test, practically all of the weight changes of the samples for all the fuels as well as the majority of the dimensional changes for heptane and toluene are positive. In SR-6 nearly one half of the changes in length and width, and over one half of the changes in thickness are negative. The positive changes indicate that there is some retention of liquid accompanied by a slight swelling. Considering the magnitude of the changes for each sample in the three fuels regardless of sign, in the majority of cases the greatest changes in weight, and length and width of the samples occurred in toluene, whereas in thickness, the greatest changes were fairly well distributed between toluene and SR-6. The greater positive changes obtained with toluene compared to heptane may be partly ascribed to the greater volatility of heptane.

None of the samples showed weight changes in heptane of over 0.5 per cent, and about one half of them exhibited changes of 0.1 per cent or less. In toluene, the cotton-fabric unsaturated-polyester laminate N showed a change of 2.83 per cent. The remainder of the laminates changed less than 1 per cent, and about one half of the samples showed changes of less than 0.5 per cent. In SR-6 the laminate N showed a change of 1.54 per cent. The remainder of the samples showed changes of less

than 0.35 per cent, and nearly one half of the samples exhibited changes of 0.05 per cent or less. The glass-fabric unsaturated-polyester laminate X had the smallest average change for the three fuels, with individual values of less than 0.1 per cent.

The laminate N showed length and width changes of 0.11, 0.14, and 0.16 per cent in heptane, toluene, and SR-6, respectively. The remainder of the samples exhibited changes of less than 0.1 per cent.

The cotton-fabric unsaturated-polyester laminate N in toluene and SR-6, and the low-pressure Grade C phenolic L in SR-6, showed thickness changes of 2.3, 1.2, and 1.6 per cent, respectively. The remainder of the samples changed less than 1 per cent.

The laminate X exhibited the greatest stability and the laminate N the least.

(b) **Continuous Fuel-Immersion Test.** In the continuous-immersion test the majority of the changes in weight and dimensions were positive. The

a. Code for this column:
1 = Tested immediately.
r = Tested after reconditioning for 7 days at 77° F and 50 percent relative humidity.

b. Based on average values for two specimens.

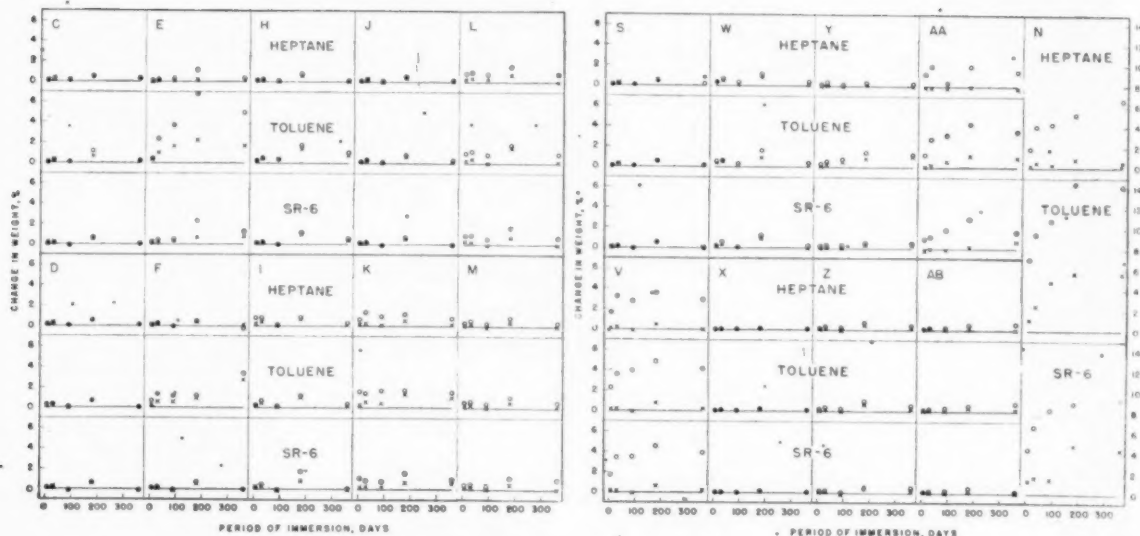

FIG. 3 CHANGES IN WEIGHT OF LAMINATES IN PROLONGED FUEL-IMMERSION TESTS
(O-tested immediately after removal from the fuel. X-tested after reconditioning for 7 days.)

FIG. 4 CHANGES IN LENGTH AND WIDTH OF LAMINATES IN PROLONGED FUEL-IMMERSION TESTS
(O-tested immediately after removal from the fuel. X-tested after reconditioning for 7 days.)

changes, regardless of sign, were equal to or higher for the "tested immediately" condition, as compared with the "reconditioned 7 days" condition in the majority of cases. In the majority of cases toluene caused the greatest changes. In weight and dimensions, the changes in the majority of cases attained their maximum values at the 180-day period. The reduction in the changes during the succeeding 180-day period indicates that the fuels may have dissolved some of the resin.

It is noted that for a given type of laminate, the weight changes varied considerably among the samples. For example, samples J, I, and W are all Grade C laminates made with the same phenolic resin. In most cases the changes for sample W for all three fuels are about double the corresponding values for sample J.

Among the glass-fabric unsaturated-polyester laminates, samples E and AA exhibited changes higher than 1 per cent in each of the three fuels during the course of the 360-day immersion tests, compared with sample X which at no time changed as much as 0.3 per cent. The cotton-fabric unsaturated-polyester laminate H showed changes roughly one tenth of those of sample N, a material absorbing greater than 5 per cent of liquid in each of the fuels.

Similar behavior, namely, a wide spread in the changes for samples of a given type of laminate, is evident (Table 5) in the thickness changes of the unsaturated-polyester laminates.

A comparison of the changes in the various samples after 360 days of immersion in the fuels follows:

FIG. 5 CHANGES IN THICKNESS OF LAMINATES IN PROLONGED FUEL-IMMERSION TESTS (O—tested immediately after removal from the fuel. X—tested after reconditioning for 7 days.)

Weight Changes at 360 Days. In heptane the cotton-fabric unsaturated-polyester laminate N and the glass-fabric unsaturated-polyester laminate AA in the "tested immediately" condition showed changes of 6.60 and 1.44 per cent, respectively. The remainder of the samples exhibited changes of less than 1 per cent, both when tested immediately and after 7 days of reconditioning. In toluene more than one half of the samples when tested immediately and more than three fourths of the materials in tests after reconditioning 7 days showed changes of less than 1 per cent. In SR-6 the laminates N, E, and AA in the tested immediately condition, and the laminate N in the 7-day condition showed changes of 9.32, 1.30, 1.65, and 4.34 per cent, respectively. The remainder of the samples had changes of less than 1 per cent. The lignin paper laminate D, the Grade C phenolic laminate J, and the glass-fabric unsaturated-polyester laminate X have the least average changes for all fuels, and both test conditions with no individual changes greater than 0.3 per cent.

Length and Width Changes at 360 Days. The laminate N in heptane and SR-6, and the laminates F, H, K, and N in toluene showed changes greater than 0.1 per cent. The remainder of the samples exhibited changes of 0.1 per cent or less.

Thickness Changes After 360 Days. The unsaturated-polyester laminates F, N, and X in heptane, E, F, N, Y, and AA in toluene, and N and AA in SR-6 showed changes greater than 0.6 per cent in either test condition or both. The remainder of the samples had changes of 0.6 per cent or less.

Changes in Flexural Properties. The changes in flexural strength and flexural modulus of elasticity of the laminates after immersion in heptane, toluene, and SR-6 are shown in Table 6 for cyclic fuel immersion, and in Tables 7 and 8 and Figs. 6 and 7, for continuous fuel immersion. The laminates exhibiting losses greater than 10 per cent for flexural strength and 5 per cent for flexural modulus of elasticity in the cyclic fuel-immersion test, and after 360 days of continuous fuel immersion are listed in Table 9. The data for the low-pressure Grade C phenolic laminate V were not included in the tables and in the discussion because of its great variability but are shown in Figs. 6 and 7.

(a) Cyclic Fuel-Immersion Test. In the cyclic fuel-immersion test approximately two thirds of the changes in flexural strength and in flexural modulus of elasticity are negative in each fuel.

Considering the changes for each sample in the three fuels, it is noted that the losses are well distributed among the three fuels. The Grade AA phenolic laminate K exhibited the greatest positive changes in all three fuels in both flexural strength and flexural modulus of elasticity, although the initial values of these two properties for sample K are among the lowest.

Of the eighteen samples tested in each fuel, only four, none of which was a cotton-fabric phenolic, had losses in flexural strength greater than 5 per cent. Two samples, the glass-fabric unsaturated-polyester laminate E, and the cotton-fabric unsaturated-polyester laminate N had losses greater than 10 per cent in each of the three fuels.

Approximately one half of the materials exhibited losses in flexural modulus of elasticity less than 5 per cent in each fuel. Only the enameled-cotton-fabric unsaturated-polyester laminate H and the Grade L phenolic laminate J had losses greater than 10 per cent in each of the three fuels.

The samples which showed the greatest flexural stability in the three fuels were the cotton-fabric melamine laminate M, the cotton-fabric phenolic laminate L, the high-strength-paper phenolic laminate S, the cotton-fabric unsaturated-polyester laminate F, and the glass-fabric unsaturated-polyester laminate AB. The changes in both flexural strength and flexural modulus of elasticity did not exceed 5 per cent. Samples X and K, which showed increases but no decreases greater than the foregoing limits, were considered to have withstood the cyclic immersion test favorably. The cotton-fabric unsaturated-polyester laminate N exhibited the greatest changes.

(b) Continuous Fuel-Immersion Test. In the prolonged fuel-immersion test most of the changes in flexural strength and flexural modulus of elasticity are negative. Eighty per cent of the differences in the percentage values between the "tested immediately" and "reconditioned 7 days" conditions of test for the three fuels in flexural strength and flexural modulus of elasticity are 5 or less. It is considered that differences of this order are not significant. This indicates that in the majority of cases the deterioration occurred during the immersion, and that retained solvent in the tested immediately condition had little effect on the strength and modulus of elasticity. Most of the differences for flexural strength and flexural modulus of elasticity were approximately the same for the three fuels in the two test condi-

tions; where there were exceptions, the differences were usually greatest in toluene. Most of these large differences took place in the unsaturated-polyester laminates.

At no time during the continuous-immersion test, did any cotton-fabric phenolic laminate show losses in flexural strength exceeding 10 per cent in the three fuels. This was also true of two glass-fabric unsaturated-polyester materials, X and AB, the paper-phenolic laminate S, and the rayon-phenolic laminate Z. The cellulose-filled phenolic laminates exhibited the following trend with regard to the flexural modulus of elasticity in the course of the immersion tests: After 7 days of immersion, the changes were losses, and as the test progressed the losses decreased with some samples showing gains at the end of the test. The changes for the cotton-fabric phenolic materials were about

—10 to —20 per cent at 7 days, and at 360 days the changes were about —5 to +5 per cent.

It is noted that, just as in the cyclic-immersion test, the various samples of polyester laminates varied considerably in their flexural-strength behavior on prolonged immersion.

A comparison of the changes in the flexural properties of the various samples after 360 days of immersion in the fuels follows:

Flexural Strength Changes at 360 Days. In heptane only the unsaturated-polyester laminates E, N, and Y showed losses greater than 10 per cent. In toluene the only samples that showed losses greater than 10 per cent in either test condition were all unsaturated-polyester laminates. Samples X and AB were the only materials of this type which did not exceed 10 per cent loss. In SR-6 only the unsaturated-polyester laminates E, N,

^a The letters are the designations for the laminates tested as shown in Table 1. Due to the variability of the V material, it was not included in this summary.

and Y showed losses greater than 10 per cent. In each of the three fuels and for both test conditions, nearly one half of the samples had losses greater than 5 per cent. The Grade AA phenolic laminate K was the only material which exhibited increases for both test conditions in each of the three fuels:

Flexural Modulus of Elasticity Changes at 360 Days. In heptane none of the samples exhibited losses greater than 5 per cent for either test condition. In toluene the unsaturated-polyester laminates X and Y showed losses of 1 per cent or less in either test condition. The remaining unsaturated-polyester laminates showed losses of 5 per cent or more. In SR-6 the only samples which had losses greater than 5 per cent in either test condition were the unsaturated-polyester laminates E, N, and AB, and the lignin-paper laminate D. The phenolic laminates K, L, and S, and the melamine laminate M were the only samples which exhibited increases for both test conditions in all three fuels, and the phenolic laminate K had the largest increases.

The only sample which exhibited changes not exceeding 5 per cent^b in both flexural strength and modulus of elasticity after 360 days of immersion in each fuel was sample J. Other samples exhibiting satisfactory behavior were the asbestos-fabric phenolic laminate K, which exhibited positive changes, and the cotton-fabric phenolic laminates L and W, which showed no losses greater than 5 per cent but whose increases were more than 5 per cent in some instances. The cotton-fabric unsaturated-polyester resin laminate N showed the greatest losses in flexural properties.

CONCLUSIONS

The following conclusions refer to the actual numerical results obtained in this investigation. Since there may be appreciable differences in the properties of individual sheets taken from the same batch, in different batches made by the same manufacturer, and in similar laminates made by different manufacturers, any general inferences drawn from these data about a given type of laminate should be considered tentative.

^b Changes in the flexural properties less than 5 per cent are not considered significant due to the variability of the material.

1 No one sample exhibited smaller changes than all the other samples in all properties for all fuels and for both cyclic and continuous immersion.

2 In all three fuels, the weight changes of the majority of the laminates were less than 1 per cent in the cyclic test, and did not exceed 1.5 per cent after 360 days of continuous immersion. The largest weight changes were usually obtained with the unsaturated-polyester laminates in toluene.

3 With very few exceptions, mainly cotton-fabric unsaturated-polyester samples, the length and width changes after either the cyclic or the 360-day immersion in the fuels did not exceed 0.1 per cent. In both types of test the changes in thickness were, in the majority of cases, less than 1 per cent. The exceptions occurred mainly in the 360-day immersion test for several unsaturated-polyester laminates in toluene.

4 The best weight and dimensional stability in all three fuels in the cyclic test was observed with the glass-fabric unsaturated-polyester laminate X.

5 After the 360-day immersion test, the weight and dimensional changes were, in the majority of cases, higher for the samples when tested immediately as compared with measurements after reconditioning for 7 days.

6 The changes in flexural strength for the cyclic test and after the 360-day immersion test were, in the majority of cases, negative. However, the losses were less than 10 per cent for all samples, except some unsaturated-polyester laminates. For the latter samples in the 360-day test, greater losses usually occurred in toluene than in the other fuels.

7 The changes in flexural modulus of elasticity were, in the majority of cases, negative in the cyclic and the continuous-immersion tests. In the cyclic test no losses greater than 10 per cent were shown by the samples, except one phenolic laminate and several unsaturated-polyester samples. After 360 days of immersion, no losses greater than 10 per cent occurred except for some unsaturated-polyester laminate samples in toluene or in SR-6 or in both.

8 The unsaturated-polyester laminate samples varied widely among themselves in regard to the magnitude of the change in a given property after the immersion tests.

Current Design Practices for Gas-Turbine Power Elements

By H. D. EMMERT,¹ MILWAUKEE, WIS.

A brief description is presented of certain principles of design and analysis for power elements of commercial gas-turbine plants. These principles are based upon the experience of the gas-turbine engineering group of the author's company. The discussion comprises a review of procedures for analysis of turbine performance and design of blading and blade-carrying elements. Since the mechanical reliability and useful service life of a gas-turbine plant are governed almost entirely by the design of the power element, such a design must be a compromise between requirements for high efficiency, dependability, and low first cost. The fulfillment of these requirements is assisted by the organization of fundamental principles and experience into basic design practices.

INTRODUCTION

NUMEROUS technical discussions have been published concerning the general features and potentialities of gas-turbine plants for land, marine, and air service. This paper is restricted to the consideration of a single component of the gas-turbine plant, namely, the basic power element. The problems under discussion comprise (a) the design of the turbine blade path from the standpoint of fluid mechanics, and (b) the basic principles of stress analysis used for the blades and blade-carrying elements. The mechanical construction of such parts as casings, bearings, supports, and governors is not included.

GENERAL DESIGN PRINCIPLES

Importance of Optimum Design. The net output of a gas-turbine plant is represented by a surplus in power produced by an expansion element over the power demand of a compression element. On an average, the ratio of gross power to net power is of the order of 2 or 3 to 1. Assuming a constant compressor demand, an increase of 1 per cent in turbine efficiency results in a gain of from 2 to 3 per cent in net output and efficiency. This indicates the importance of improving power-element performance to the maximum practical level.

Mechanical reliability and useful service life of a gas-turbine plant are governed to a large degree by the design of the power element. In this element occurs the particularly critical combination of high temperature and high dynamic stress. Reliability and long life are of primary importance for commercial turbines. These requirements are reflected by a tendency toward conservatism in temperature and stresses in such machines when compared with aircraft-turbine practice. Since performance requirements for commercial applications do not permit any appreciable sacrifice in fuel economy, it is necessary to offset the effects of moderate cycle temperatures by increasing

power-element efficiencies at some expense in over-all weight and size.

Basic Turbine-Design Principles. The most important factors which control the type of construction adopted for any specific gas turbine are as follows:

- (a) Desired efficiency level.
- (b) Expected useful service life.
- (c) Required maximum-load capability.
- (d) Desirable variable-load characteristics.

The particular problems associated with commercial applications indicate that certain design principles have definite advantages:

1 The premium placed on performance almost invariably results in the employment of a multistage construction. Turbine efficiency is thereby considerably improved over the level which can be obtained with the lightweight single-stage turbines ordinarily used in aircraft units.

2 The large volumetric flows inherent in high-capacity designs necessitate correspondingly large annular flow areas. These are best provided by high ratios of active blade height to blade-rising mean diameter. Three-dimensional flow considerations therefore become of considerable importance, and the mechanical design of the blading and spindle becomes more difficult.

3 High speeds are desirable to reduce physical size as much as possible. Procurement of large ingots is difficult with many of the better gas-turbine alloys. In addition, handling and fabricating problems in the shops increase rapidly with size of part.

The foregoing principles lead to the conclusion that the most practical design for commercial application is one incorporating a plurality of stages, employing maximum blade-height ratios in the low-pressure elements, and rotating at a maximum speed. Fig. 1 shows a cross section through the blade path of such a turbine, this particular design being representative of units intended for commercial power applications.

BLADE-PATH DESIGN AND PERFORMANCE ANALYSIS

Turbine Efficiency. The internal efficiency of a turbine relates the actual power produced by the turbine stages to the theoretical power available in an isentropic expansion from the total pressure and temperature at the turbine inlet to the static pressure at the turbine exhaust. It is a function of the following basic variables

$$\eta_i = (\eta_s)(RF) - \% \Delta h_L \dots \dots \dots [1]$$

where

- η_i = internal efficiency, per cent
 η_s = average stage efficiency, per cent
 RF = reheat factor
 $\% \Delta h_L$ = leaving loss, per cent

The stage efficiency takes into account the losses incurred in each element due to gas friction and leakage. It is primarily dependent upon the operating conditions and configuration of the staging, and it can be controlled within fairly wide limits by the designer.

The reheat factor originates from the fact that as the gas

Fig. 1 Cross Section Through Typical Commercial Gas-Turbine Power Element

progresses through the blading, friction and leakage cause the actual temperatures to be slightly above those corresponding to an expansion without losses. This has an apparent effect of increasing the over-all efficiency slightly above the incre-

Fig. 2 Reheat Factors for Gas-Turbine Expansions
(Curves are based upon a mean-specific-heat ratio of 1.350.)

mental stage efficiency. Fig. 2 shows a reheat-factor plot computed from the following formula (1)²

$$RF_{\infty} = \frac{1}{\eta_s} \left[\frac{1 - \left(\frac{p_2}{p_1} \right)^{\eta_s \frac{k-1}{k}}}{1 - \left(\frac{p_2}{p_1} \right)^{\frac{k-1}{k}}} \right] \dots \dots \dots [2]$$

where

RF_{∞} = reheat factor for infinite stages
 p_1 = turbine inlet pressure
 p_2 = turbine exhaust pressure
 k = mean-specific-heat ratio

² Numbers in parentheses refer to the Bibliography at the end of the paper.

Leaving loss is proportional to the residual kinetic energy contained in the gas leaving the turbine. Shaft power is generally the only useful output from a commercial gas turbine, and residual kinetic energy is unavailable for further use. The magnitude of the leaving loss is primarily dependent upon the relation between the total volumetric flow of gas and the annular flow area at the last row of blades. The large volumetric flow in high-capacity units necessitates the use of a considerable amount of exhaust annulus area if the leaving loss is to be held to an acceptable value.

Stage Performance. Both theory and experience indicate that the following basic factors almost completely control the performance of an individual stage:

- 1 Primary factors: (a) Isentropic velocity ratio
 (b) Stage reaction
 (c) Leakage configuration
- 2 Secondary factors: (a) Pressure ratio
 (b) Parasitic losses
 (c) Viscosity effects

Numerous tests have shown that isentropic velocity ratio is the most important criterion establishing general performance level of a stage, regardless of the actual physical configuration. This parameter measures the energy loading for the stage and is defined by the following relation

$$\frac{u}{c_0} = \sqrt{\frac{\Delta h_u}{\Delta h_s}} \dots \dots \dots [3]$$

where

u = blade velocity at blade-ring mean diameter, fps
 c_0 = gas velocity corresponding to stage isentropic enthalpy drop, fps

$$\Delta h_u = \text{stage equivalent blading energy, Btu per lb} \\ = \frac{u^2}{2gJ}$$

$$\Delta h_s = \text{stage isentropic enthalpy drop, Btu per lb} \\ g = 32.17 \text{ ft/sec}^2 \\ J = 778.26 \text{ ft-lb/Btu}$$

For a given set of blading operating with a moderate pressure drop, changes in flow kinematics within the blading are adequately reflected by changes in the isentropic velocity ratio. Fig. 3 shows two examples of basic blading-efficiency curves as derived by test. Curves such as these represent blading performances only, and stage efficiencies ordinarily will be somewhat lower due to the effects of other factors.

As a general rule, the number of stages to be employed in a specific turbine design is determined from the selection of a

* Reaction-turbine designers customarily use the isentropic drop per row, rather than per stage, in Equation [3]. However, the use of the stage drop is more general in application.

desirable velocity ratio at the normal operating load. The curves in Fig. 3 show that high velocity ratios are required for good efficiency. However, the number of stages rises rapidly as the velocity ratio increases. A considerable amount of investigation of each design is necessary to obtain a satisfactory balance in this respect.

The second major factor affecting stage performance is the stage reaction. This parameter is best explained by reference to Fig. 4 which shows the energy quantities in a stage on an enthalpy-entropy diagram. The expansion through a stage is accomplished in two distinct steps, namely, a partial expansion

through the fixed blade ring, followed by an additional expansion through the moving blades. The distribution of energy assigned to these two successive expansions is at the control of the designer and is established by means of the stage reaction. Stage reaction is defined as the ratio of the isentropic enthalpy drop across the moving blades to the isentropic enthalpy drop across the stage.

Two opposing considerations influence the amount of reaction used in a specific turbine. Purely from the performance standpoint, it is preferred to use a stage reaction of approximately one half. This corresponds to the conditions in normal reaction blading, and maximum efficiency is obtained provided velocity ratio is high and leakage losses are low. If the turbine isentropic enthalpy drop is large, the number of stages may become excessive. When this occurs it is frequently desirable to decrease the number of stages by decreasing the average velocity ratio of the high-pressure elements. The reaction in these elements is also lowered, and they assume the form of a normal impulse-blading configuration. This is particularly desirable when high temperatures and stresses are involved, since a reduction in stage reaction lowers the effective impact temperature on the moving blades.

Leakage control plays a dominant part in establishing stage efficiency level. Gas leakage through operating clearances between rotating and stationary parts represents a loss of working fluid. It is therefore desirable that clearances be kept to the minimum value consistent with reliability, and that the leakage gas path be made as tortuous as possible.

Both shrouded and open-ended blades are used. For blades operating at high tip velocities, shroud weight adds considerably to the centrifugal stress at the blade base. If the blade is long, the leakage and end-loss effects can be kept small and at the same time safe operating clearances at the blade tip can be maintained. Open-ended construction is preferred in such a design (see Fig. 1). Leakage control for short blades is better if shrouding is installed.

Spindle glands are normally designed with step-type labyrinth seals similar to those shown in Fig. 1. This same construction is used for interstage seals in disk-and-diaphragm blade paths. Accurate tests have been made and correlated by simple theory (2) to determine the leakage characteristics of various types of seals. The performance with air of a typical standard labyrinth design is summarized in Fig. 5.

Pressure ratio is listed as a secondary factor influencing stage performance. For single-stage turbines, pressure ratio may become of major importance. Compression shock losses and poor control of fluid direction may seriously depreciate efficiency

FIG. 5 LEAKAGE FLOW CHART—SUMMARY OF TESTS OF STEP-TYPE SPRING-BACK LABYRINTH SEAL

when high pressure drops are employed across individual elements. However, the pressure ratio across each stage of a multistage turbine is generally small, with a corresponding decrease in influence on the individual elements. The Mach number of the mean fluid stream relative to the blading seldom exceeds about 0.65. This magnitude causes little difficulty due to shock or choking as long as the flow is accelerated.

Parasitic losses resulting from disk or spindle gas friction are not high in gas turbines of the type under consideration. However, they are accounted for in performance estimation through empirical formulas derived from test analysis.

The influence of viscous forces within turbine staging is measured by the Reynolds number. Laboratory tests on small turbine elements are known to indicate a Reynolds-number effect, but the importance of this factor has not been apparent from tests on full-scale commercial turbines. The influence is sufficiently small in large units so as to be indeterminate in the presence of other more powerful factors.

Basic Stage Analysis. Requirements for optimum performance at high speed make it necessary in most cases to design the blading configuration for a new turbine to conform to a specific application. It is therefore essential that there be available detailed procedures for turbine-stage analysis. The designer is thereby able to predict the approximate actual conditions existing within each element and can proportion the blades accurately with respect to shape and setting.

Blading analyses by means of filament-flow theory and vector diagrams are as old as the steam-turbine art, but these conceptions still represent the most powerful tools available to the practical gas-turbine designer. Two basic requirements must be met in applying vector diagrams to blading performance and flow analysis:

- 1 The velocity magnitudes must represent integrated mean values rather than highly peaked or depressed local values.
- 2 The velocity directions must represent mean fluid directions, and not necessarily blade-profile geometric angles.

Cascade tests have contributed to a certain extent to the alignment of current design information, but the main source of data has always been analyses of over-all turbine tests. Actual working procedures are admittedly oversimplified from the viewpoint of the highly developed mathematics of modern aerodynamics. It cannot be assumed that the actual flow conditions within a stage are in exact agreement with predictions from simplified vector-diagram analyses. However, reasonable correspondence between prediction and performance has been thoroughly demonstrated, provided suitable control is exerted by continual comparison with test results.

The basic variables in blade-ring calculations are shown in Fig. 6. The data apply to either fixed or moving blades, provided the velocity magnitudes and directions are taken relative to the blade ring under consideration. The most important quantity required in blade-ring analysis is the effective kinetic energy at the ring outlet. This energy is computed from the following relation

$$\Delta h_{e2} = \phi^2_E (\Delta h_{e1} + C_i \phi^2_i \Delta h_{e1}) \dots \dots \dots [4]$$

where

ϕ^2_E = expansion-energy coefficient

C_i = incidence coefficient

ϕ^2_i = kinetic-energy coefficient

See Fig. 6 for other symbols.

The primary loss resulting from turbulence and wall friction within the blade passage is reflected by the expansion-energy coefficient. This coefficient is determined from the profile

BLADE RING DATA:—

- b = AXIAL WIDTH, IN.
- β_1 = BLADE INLET ANGLE, DEG.
- O = THROAT OPENING, IN.
- P = CIRCUMFERENTIAL PITCH, IN.
- O/P = OPENING COEFFICIENT
- β_2 = ANGLE OF EFFLUX, DEG.
- $\gamma = \sin^{-1}(O/P)$ (SEE FIG. 12)
- θ = DESIGN DEFLECTION ANGLE, DEG. $\theta = 180^\circ - (\beta_1 + \beta_2)$

GAS FLOW DATA:—

- ϕ_1 = GAS INLET ANGLE, DEG.
- i = INCIDENCE ANGLE, DEG.
- $\phi_1 = \phi_1 - \phi_1$
- w_1 = INLET VELOCITY, FPS
- w_2 = EFFECTIVE OUTLET VELOCITY, FPS
- Δh_{e1} = KINETIC ENERGY AT INLET, BTU/LB.
- Δh_{e2} = ENTROPIC ENTHALPY DROP, BTU/LB.
- Δh_{e2} = EFFECTIVE KINETIC ENERGY AT OUTLET, BTU/LB.

FIG. 6 BLADE-RING ANALYSIS

FIG. 7 VARIATION OF EXPANSION-ENERGY COEFFICIENT WITH DESIGN DEFLECTION ANGLE

width and deflection angle, as shown in Fig. 7. Tests indicate that the effective energy obtained from a given amount of inlet kinetic energy is less than that which is realized when the same quantity of available energy is supplied by pressure drop. In Equation [4] the inlet kinetic energy is reduced by a kinetic-energy coefficient. This coefficient is normally assumed to be equal to the expansion-energy coefficient. The rule is rough, but it is justified by an elementary theory of blade friction loss. (3). When the inlet velocity vector forms a definite incidence angle with reference to the blade leading edge, an additional loss occurs which is evaluated by means of the incidence coefficient. This coefficient is a function of the blade-nose design and the angle of incidence as shown in Fig. 8.

The angle of efflux from the ring is assumed to be approximately equal to arcsine (O/P) , where O is the blade throat opening and P is the blade circumferential pitch. The accuracy of this simple rule is adequate for small efflux angles. It is discussed in more detail in a later section.

Establishment of the average velocity magnitudes and directions within a stage permit the determination of tangential velocity components. Estimated blading output per pound of gas flow may then be found by entering these data into the basic turbine equation

$$\Delta h'_w = \frac{u_1 c_{t1} - u_2 c_{t2}}{gJ} \quad [5]$$

where

$\Delta h'_w$ = blading output, Btu per lb

u_1 = blade velocity adjacent to the fixed-ring outlet mean diameter, fps

u_2 = blade velocity at the outlet mean diameter of the moving ring, fps

c_{t1} = tangential component of effective velocity leaving fixed ring, fps

c_{t2} = tangential component of velocity leaving stage, fps

The gas flow is found from the continuity equation using the effective velocity, area, and gas density at the blade-ring throat. Net stage output may then be calculated by subtracting clearance and parasitic losses from the gross blading output.

Three-Dimensional Considerations. Radial variations in circumferential pitch between blades increase as the blading is lengthened. If the blades are installed with normal pitch at the blade-ring mean diameter, the pitch at the tip may become excessive and result in poor control of fluid direction. At the inner radii, the pitches may become so small as to restrict the gas considerably. Furthermore, unless the flow is controlled properly, the tangential velocity components along the outlet plane of the fixed blade ring tend to throw the fluid outward. This

centrifugal action results in a massing of the flow toward the tips and a starving of the blade passages at the roots.

The three-dimensional flow problem has been attacked quite thoroughly using approaches based on aerodynamic theory. For practical purposes, however, a simple and adequate solution is obtainable from rather elementary conceptions. The basic elements of the problem are presented in Fig. 9. The upper diagram shows the velocity components of a fluid stream leaving a fixed ring of blades at a given radius. In the lower diagram the same velocities are projected onto the outlet plane of the blades. Consideration of the forces acting on an incremental mass of gas indicates that the static pressure at the fixed-ring outlet must gradually increase with radius in accordance with the following equation

$$\frac{dp}{dr} = \rho \frac{c_t^2}{r} \quad [6]$$

where

p = static pressure at fixed-ring outlet, psfa

r = radius, ft

ρ = mass density of gas, lb-sec²/ft⁴

c_t = tangential component of velocity leaving fixed ring, fps

Three controlling premises are made in the practical design of blading where special provision is to be incorporated for maintenance of radial equilibrium:

- 1 The basic equation for radial stability of flow, as given in Equation [6], is to be satisfied over the entire outlet plane of the fixed blade ring.
- 2 The mass flow through the stage is to be distributed evenly over the entire stage annulus.
- 3 The isentropic enthalpy drop across the stage is to be constant at all radii in the stage annulus.

Stages designed in accordance with these conceptions exhibit the following characteristics:

- 1 The fixed blades have almost symmetric profiles at all radii.
- 2 The moving-blade profiles vary with radius. At the inner radius, the profile shape approaches that of a normal impulse blade. An approximately normal reaction-blade profile is used at the mean radius. At the tip, the profile assumes the form of a low-cambered airfoil of medium thickness.

Analyses of tests on both steam and gas turbines incorporating such blading have indicated that appreciable improvements in efficiency are attained in comparison with more conventional designs. In addition, improved accuracy has been obtained with respect to prediction of mass-flow characteristics.

Turbine Performance. The performance of a complete turbine depends primarily upon the characteristics of the individual stages composing the turbine. However, it is essential that the design be established and controlled from the standpoint of the complete unit, rather than as an assembly of completely independent elements. Poor design of any one stage affects elements both upstream and downstream from that point. The residual kinetic energy from each stage except the last is available to the succeeding stage. With adequate care in design, this energy is recoverable to a large extent.

Other factors than stage design may have appreciable effects on performance. Pressure drops in the inlet and exhaust passages are particularly important. Low velocities, gentle changes in flow direction, and freedom from obstructions are essential if harmful reductions in both performance and load capability are to be prevented (4). Radiation losses may reach significant values in high-temperature units, particularly at light load. Adequate insulation is mandatory, not only for the turbine proper

FIG. 8 VARIATION OF INCIDENCE COEFFICIENT WITH INCIDENCE ANGLE

FIG. 9 VELOCITY COMPONENTS AND FLUID FORCES AT FIXED-BLADE-RING OUTLET

but also for all interconnecting piping handling hot gas. Mechanical losses, as imposed by bearings, reduction gears, and lubrication and governor oil pumps, are generally small for commercial gas turbines.

Over-all turbine performance is determined analytically by combining the results of stage calculations and then correcting for the external effects just discussed. Dimensional analysis assists in correlating the influences of the various factors. For practical purposes the performance of a given turbine can be represented adequately in terms of the following simplified parameters.

$$\left(\frac{W \sqrt{T_{01}}}{p_{02}} \right), (\eta_t) = f \left(\frac{p_{01}}{p_{02}} \right), \left(\frac{n}{\sqrt{T_{01}}} \right) \dots \dots \dots [7]$$

where

- W = gas flow, lb per hr
- T_{01} = total temperature at inlet, deg F abs
- p_{01} = total pressure at inlet, psia
- p_{02} = static pressure at exhaust, psia
- η_t = internal efficiency, per cent
- n = turbine speed, rpm

Fig. 10 is a general performance map in terms of these parameters for a turbine rated at 12,000 gross bhp. The calculation of

FIG. 10 TYPICAL GAS-TURBINE POWER-ELEMENT PERFORMANCE MAP

such a chart represents the final step in the thermodynamic analysis of each turbine design. The accuracy of the over-all design procedure is measured by the degree of correlation on such a chart between computed and test performance.

TURBINE-BLADE DESIGN

Standard Blade Profiles. Each steam-turbine manufacturer has conducted over a period of years extensive shop and field tests on the blading configurations used in his particular turbine designs. These programs have resulted in a standardization within each company of not only blade profiles but also blade pitches and settings for the best compromise between efficiency and cost (5).

A number of commercial gas turbines have been built utilizing standard blade profiles of various types. These machines have given excellent performance within their normal ranges of application. The general trend, however, has been toward higher rotative speeds with the accompanying advantages of reduced size and weight. Ratios of blade length to mean diameter are of necessity increased in such machines, and considerations of both

three-dimensional flow effects and blade stresses have led to the general adoption of blades with warped surfaces and high degrees of taper. Standard profiles are, therefore, not ordinarily applicable, and each new turbine design requires special profile development to some degree.

Basic Profile-Design Principles. The significant dimensions and angles used to control profile design are illustrated in Fig. 11. The most important parameter is the opening coefficient, which is defined as the ratio of the minimum passage width or throat opening between adjacent blades to the circumferential pitch of the blades. Control of both fluid efflux angle and mass flow is exerted primarily by means of the opening coefficient. As long ago as 1924, test data published by the Steam Nozzles Research Committee in England (6) showed that, for the particular nozzles and blades tested, the fluid angle was given quite closely by arcsine (O/P). Subsequent tests, both published and unpublished, have verified this approximate relationship within a reasonable range. General experience indicates that the curve in Fig. 12 provides a relatively accurate guide. The curve shows an increasing deviation of the fluid angle from arcsine (O/P) as the opening coefficient is increased.

FIG. 11 PROFILE AND BLADE-RING NOMENCLATURE

FIG. 12 VARIATION OF EFFLUX ANGLE WITH OPENING COEFFICIENT

Blading performance is affected to a large extent by the aerodynamic loading on the profiles. The resultant force acting on a profile corresponds to the integrated pressure differences between the convex and concave surfaces. In closely pitched blades, these pressure differences and their accompanying turbulence losses are reduced. However, losses due to surface friction are increased. Wide pitching decreases surface-friction loss, but aerodynamic loading is increased. This may induce stalling with an accompanying rapid drop in performance.

Aerodynamic loading is a function of the cascade solidity or chord/pitch ratio. The permissible ranges of blading solidity for

standard profiles have been fairly accurately established by test. Complete correlation of test results has not been attained for all types of profiles over the range from sharp-edged high-deflection impulse blades to low-camber small-deflection airfoils. However, sufficient data to permit interpolation between known optimum settings have been assembled and interpreted in terms of an aerodynamic loading coefficient (7).

For the practical design of a blade, vector diagrams at control points along the blade height are established from the data in the previous sections. The requirements for fixed blade rings are generally such that normal reaction profiles can be used. The contours, pitches, and settings at all radii are established from experience with such configurations. The vector diagrams for long moving blades require that the profiles be varied along the radius. The fluid deflection angle at the blade base is generally large, and highly cambered, closely pitched profiles must be used. Depending upon the stress conditions and the root design, a ratio of circumferential pitch to axial width of from 0.45 to 0.60 is ordinarily selected. The profile at the tip is normally designed as a low-camber airfoil of medium thickness. The aerodynamic loading coefficient is brought into use here, the solidity being established such that the loading coefficient does not exceed a permissible maximum value.

Blade Layout. Required blade pitches, throat openings, and axial widths or chords are established by application of the principles described in the previous paragraphs. Profiles are then laid out with the following considerations for guidance:

- 1 The stress in a blade due to centrifugal force is proportional to the blade volume above the point of stress. Profile thicknesses and cross-sectional areas must therefore be closely controlled within limits prescribed by preliminary stress analysis.

- 2 Geometric inlet and outlet angles are set at approximately the desired fluid angles. Exact correspondence is not necessary and is seldom obtained. The selection of inlet angle varies with the partial-load performance requirements for the stage and turbine.

- 3 Profile nose design depends upon stress conditions and fluid velocities. Moderately small nose radii are ordinarily prescribed. Trailing-edge thicknesses are consistent with the particular manufacturing process to be used and vary from approximately 1 per cent of the chord to not over 8 per cent of the throat opening.

It is considered essential that the passage area between adjacent blades converge at all points in the direction of flow. The walls of the passage as formed by the blade surfaces are kept

free of sharp changes in radius of curvature. The actual contours of the profiles are described by combinations of either circular arcs or parabolic arcs, depending upon the desired degree and rate of change of curvature. Fig. 13 shows a set of profiles designed in accordance with these principles.

For ease in manufacture, it is usually desirable that the blade surfaces between the base and tip profiles be in the form of warped conical surfaces generated by a series of straight lines. Such a design greatly simplifies the diemaking problem for forged and cast blades. It is essential when the blades are to be produced by standard machining processes.

The moving blading of a stage designed in accordance with these general procedures is shown in Fig. 14. The stage efficiency determined by test for the element incorporating this particular wheel is approximately 88 per cent at the design conditions. This indicates the general performance level obtainable from such blading.

FIG. 14 BLADED GAS-TURBINE DISK

MATERIALS AND DESIGN STRESSES

High-Temperature Materials. There are many considerations which influence the selection of materials for gas-turbine construction. Of necessity, a limited number of criteria must be established to permit direct comparisons of available alloys, and certain properties must be adopted for quantitative use in design calculations.

Allowable working stresses in high-temperature portions of the blade path are based on rupture strength. Adequate 1000-hr stress-rupture data are available for nearly all materials considered applicable to commercial gas-turbine use (8). Consequently, little extrapolation of data is necessary for relatively short-service-life designs. Some uncertainty is generally involved for long-life turbines, but extrapolation is a relatively safe procedure as long as it is limited to approximately one logarithmic time cycle, and ductility can be predicted to remain sufficiently high. Materials which show a tendency toward brittle failure in long-time rupture tests are avoided.

For parts operating at moderate temperatures, the use of yield strength as a design stress criterion has been adopted from steam-turbine practice. Adequate yield strength is essential to prevent harmful deformations due to pure overstressing. Judgment must be exercised, however, since for most alloys yield strength and ductility vary somewhat inversely. Low ductility has been considered acceptable in certain cases, but it is believed that adequate test-bar elongation must be maintained in materials for large thick parts, particularly since uncertainty exists with many alloys regarding changes in ductility over extended periods of time at high temperature.

At the present time, creep-rate and total-deformation data

FIG. 13 TYPICAL MOVING-BLADE PROFILES

are seldom used for establishing actual working stresses for rotating parts. Stresses which are considered to be permissible from the standpoints of rupture strength and yield strength generally correspond to low values of total deformation. Such deformations are slow and steady in nature and are subject to determination by periodic inspection after a machine has been placed in operation.

Fatigue strength at operating temperature is of considerable importance in selecting blade materials. Accurate fatigue data are not available for many high-temperature alloys, and some materials exhibit no well-defined endurance limit, particularly where conditions conducive to stress corrosion are also present. Compensation for inadequate fatigue data is obtained by keeping bending stresses low and controlling blade vibrational characteristics.

Selection of Design Stresses. The present state of knowledge concerning the effects of temperature on metals and the actual temperatures and stresses encountered by parts within a turbine, do not in most cases justify overly complex methods of stress analysis. Discrepancies involved in using simple analyses adequately controlled by experience are less than the errors inherently present due to variations in properties of materials and to unpredictable stresses. These considerations make essential the use of moderate design stresses.

The important principles governing the choice of permissible working stresses are:

- 1 The machine must be protected against failure due to either fracture or excessive local deformations, under any anticipated load conditions.
- 2 Protection must be provided against unavoidable variations in properties of the materials as installed. Unwarranted rejections of materials for large machines lead to costly delays in manufacture and shipment.
- 3 Some margin is essential due to inaccuracies in stress analysis. These inaccuracies result primarily from a lack of complete knowledge of the true stresses existing in many parts. They also arise to some extent from the use of certain simplified stress-analysis procedures which are tolerated only for the purpose of shortening engineering time.

Of the many types of stresses which are encountered in gas-turbine design, average stresses in tension, compression, shear, and bending are most easily determined. Therefore they are used as the guiding criteria. Local high stresses due to stress raisers of various types are taken into account where necessary by stress-concentration factors. In many cases, such stresses are safely relieved by local yielding without failure, as a result of the plasticity of the material at operating temperature. Variable stresses are generally estimated from computed average bending stresses.

The selection of working stress is based on the operating temperature of the part and the specified service life for the turbine. For a given operating temperature, service-life considerations lead to a wide variation in permissible working stress. As a general rule, turbines are classified as short-life units if their expected-life cycle at maximum temperature is less than 10,000 hr, and as long-life units if the corresponding time is 10,000 hr or more.

The type of materials-data curve shown in Fig. 15 is used for general gas-turbine design calculations. The practical value of this type of presentation lies in the fact that all parts of a given turbine are normally designed for the same life, but large differences in operating temperature exist between the high and low-pressure ends of the unit. The appropriate working stress for a particular part is determined by applying the selected factors

FIG. 15 MATERIALS-DATA CURVE—WROUGHT S-590 10,000 HOURS

of safety to the material properties at the proper temperature ordinate.

STRESS ANALYSIS

Blade Stresses. Blading stress analysis is concerned with a determination of the stresses set up by the centrifugal and bending forces generated by rotation and fluid pressure differences. The highest stresses encountered are almost invariably those resulting from centrifugal forces in the rotating parts. The tensile stress imposed on the base profile of a blade by centrifugal force can be calculated from the following formula

$$s_c = 4.52 \gamma f_1 A \left(\frac{n}{1000} \right)^2 \dots \dots \dots [8]$$

where

- s_c = average tensile stress, psi
- γ = specific weight of blading material, lb per cu in.
- f_1 = taper factor
- A = annular area of blade ring, sq in.
- n = rotative speed, rpm

The taper factor is unity for constant-cross-section blades and, assuming constant density of blading material, the stress becomes a function of only annular area and speed. Tapered blades are used where the installation of constant-section blades would result in excessive stresses. The amount of taper permitted in any particular blade is dependent upon the degree to which both flexural strength and efficient blade shape can be maintained. Fig. 16 shows the stress reduction which can be accomplished with various degrees and types of taper.

Basic bending stresses are generated by changes in gas velocity through the blades and by static pressure differences across the blades. Axial and tangential forces per unit length of blade are determined from the estimated flow conditions in the stage. Integration of these forces yields total component loads from which are determined the moments acting on any given profile of the blade.

The maximum stress in a blade is generally at the concave side of the leading edge of the base profile, since the stresses due to centrifugal force and gas bending force are additive in tension at this point. The total tensile stress resulting from centrifugal force and average bending force therefore constitutes the maximum steady stress in the blade. Variable stresses are expressed as percentages of the average bending stresses, and the effects of stress concentration are taken into account. As shown in Fig. 17, the maximum stresses in moving blades are

$$s_s = s_c + s_b \dots \dots \dots [9]$$

FIG. 16 VARIATION OF TAPER FACTOR WITH BLADE-PROFILE AREA RATIO

FIG. 17 ASSUMED BLADE-STRESS DIAGRAM

$$s_s = KR_s s_b \dots \dots \dots [10]$$

where

- s_s = maximum steady stress, psi
- s_v = maximum variable stress, psi
- s_c = centrifugal stress, psi
- s_b = average bending stress, psi
- K = stress concentration factor
- R_s = ripple factor

Fillet radii and thickness ratios are such that the stress-concentration factor seldom exceeds 1.5. The ripple factor is a function of the blade pitches, flow conditions, and blade frequency, and it may reach values as high as 0.5 under adverse circumstances. It is somewhat lower with blade frequencies remote from those of possible exciting forces.

Stresses as determined by the foregoing formulas are compared analytically with an assumed failure line on either an endurance limit-yield strength diagram (9) or an endurance limit-rupture strength diagram, as shown in Fig. 18. A minimum factor of safety of 2 is maintained for both comparisons. The actual stresses for use on the rupture-strength diagram are calculated at normal speed, and those for use on the yield-strength diagram are calculated at 120 per cent speed. This overspeed represents the maximum value for which commercial gas turbines

are normally designed to withstand harmful permanent deformations.

Blade-Frequency Analysis. Accurate control of blade frequency is essential to insure that vibratory stresses do not exceed the limits assumed in stress analysis. Normally, a new blade

FIG. 18 ASSUMED FAILURE DIAGRAM

design is analyzed and suitably modified so that the frequency corresponding to the first mode of transverse vibration lies above the fourth multiple of the maximum rotational speed. This rule has been found to be safe for gas turbines operating from combustion chambers attached by relatively long ducting. If necessary, a safe condition is assured by tuning the actual blading after installation.

The frequency of the fundamental mode of vibration of blades in a given ring is expressed by the following formula

$$f_s = 11.0 C_f \frac{k}{h^2} \sqrt{\frac{E}{\gamma}} \dots \dots \dots [11]$$

where

- f_s = standing frequency, cps
- C_f = frequency correction factor
- k = radius of gyration of base profile, in.
- h = blade length, in.
- E = modulus of elasticity, psi.
- γ = specific weight of material, lb per cu in.

For a value of unity for the frequency correction factor, the formula is identical to that for the frequency of a uniform cantilever beam of equivalent properties. The tie between theory and actual conditions is by means of the frequency correction factor. This factor takes into account blade-taper effects and in addition is dependent upon the actual geometric configuration, the type of blade fixing, and the presence or absence of shrouding and lacing wire.

Moving blades are stiffened to some extent by centrifugal force. The running frequency is calculated from (10)

$$f_r = \sqrt{f_s^2 + B \left(\frac{n}{60} \right)^2} \dots \dots \dots [12]$$

where

- f_r = running frequency at n , cps
- B = rotation coefficient
- n = rotational speed, rpm

The rotation coefficient is dependent upon the degree of blade-root fixing, the geometric shape, and the blade-height ratio. The effect of rotation is generally small, and it can be predicted with practical accuracy for normal constructions from the data in Fig. 19.

Blade vibrational characteristics are best depicted on a frequency diagram similar to that shown in Fig. 20. Safe oper-

ating speeds for the turbine may be estimated from such a chart, with allowance for the effects of possible variations in blade frequency.

Disk Design. Fig. 21 shows the local elastic-stress distribution in a disk of uniform thickness, when carrying a prescribed rim load at a given rotational speed. The theory and formulation used to determine these stresses are of long standing (11). The stresses are essentially biaxial, consisting of both radial stresses

FIG. 19 VARIATION OF ROTATION COEFFICIENT WITH BLADE-HEIGHT RATIO

FIG. 20 TYPICAL BLADE-FREQUENCY DIAGRAM

and tangential stresses. The tangential stress at the inner radius of the center-bored disk is considerably above that at the center of the solid disk, which would apparently indicate a much lower safe speed for the former type.

Experimental evidence from a number of sources tends to refute this conclusion (12). The high stress at the inner radius of the center-bored disk is, in effect, a localized stress concentration, which is relieved to a large extent by plastic flow as soon as the elastic limit of the material is exceeded. There is little reduction in load-carrying ability of the disk as a whole.

In practical design, elastic stresses are calculated in detail for blade-carrying elements mainly for the purpose of insuring maximum utilization of the weight of material put into the elements. For comparative purposes, however, the primary criterion is the average tangential stress across the disk radial cross section. This approach assumes, in effect, that the total centrifugal load due to the blades, rim, and disk proper is carried uniformly across the cross-sectional area of the disk. The formula for the average stress is expressed as follows

FIG. 21 LOCAL ELASTIC STRESS DISTRIBUTION IN DISK OF UNIFORM THICKNESS

$$s_{ta} = 28.42 \gamma \left(\frac{I}{A} \right) \left(\frac{n}{1000} \right)^2 + \frac{P}{2\pi A} \quad (13)$$

where

s_{ta} = average tangential stress, psi

γ = specific weight of disk material, lb per cu in.

I = moment of inertia of disk half section about axis of rotation, in.⁴

A = area of disk half section, sq in.

n = rotational speed, rpm

P = total centrifugal force due to rim load at speed n , lb

Overspeed tests analyzed in accordance with the conception of uniform stress distribution show much closer agreement between average tangential stress and test-bar tensile strength, than when the analysis is based on comparing local elastic stresses and test-bar strength. This is true for both solid and center-bored disks.

Normally, disk stresses as calculated by means of Equation (13) are limited to one half the rupture strength of the material for the specified service life and temperature for the part, when operating at rated speed. Rupture strength becomes of minor importance at moderate temperatures. In such cases, the average tangential stress is limited to one half the yield strength of the material at the specified service temperature, when rotating at 120 per cent of rated speed.

Disk stresses may be reduced considerably if the disk outline is profiled. Calculation of local elastic stresses is helpful in attaining the optimum degree of profiling, and disks are designed with a constant-stress form where possible. In general, thin rims and thick hubs are desirable from the standpoint of over-all stress reduction.

The effects of temperature variation may be of importance in the stressing of disks. These effects are secondary for industrial or utility turbines operating under almost constant load conditions with few start-ups and shutdowns. The temperature gradients during service are small and consistent, and the time intervals for placing the units in or out of service may be made sufficiently long to insure against any deleterious effects.

Stresses generated by thermal gradients may reach serious levels in units subjected to rapid load changes or where quick

starting is required. Since these stresses are transient in nature, they induce results similar to fatigue. This phenomenon, which is known as thermal shock, may rapidly lead to failure if not properly taken into account in the design. Without going into particulars, such conditions are best combated by preventing undesirable temperature gradients as much as possible. In this respect, experience up to the present time with artificial cooling of parts subjected to hot gas has been somewhat disappointing. Induced temperature gradients in some cases have led to deformations and failures which would not normally have occurred had the parts been permitted to assume more normal temperature distributions.

CONCLUSION

There are many problems in gas-turbine design which cannot be discussed adequately in a presentation such as this. An attempt has been made, however, to show the approaches to some of the more basic problems peculiar to the design of commercial gas-turbine equipment. These approaches are simple and systematic in all cases and they are based primarily upon fundamental theory, modified by experiment and experience.

The gas turbine is in a state of development. This development must be based upon a background of basic data which can be accumulated only through experience. Since the commercial gas turbine is in direct competition with other well-established types of prime movers, the requirements for efficiency, dependability, and low first cost must all be given special consideration. The fulfillment of these requirements is greatly assisted by the organization of fundamental principles and experience into basic design practices similar to those which have been outlined in this paper.

ACKNOWLEDGMENT

The author desires to express his appreciation to the Allis-Chalmers Manufacturing Company for permission to publish the data contained in this paper. He also wishes to acknowledge the invaluable guidance of Mr. R. C. Allen, during the preparation and review of the various drafts, and the able assistance of Mr. R. W. Rouse in preparing the final manuscript and drawings.

Discussion

D. L. MORDELL.² The writer is disappointed to see that no mention is made of the possibility of using diffusion after the turbine. Rather than regarding the residual kinetic energy as a dead loss, by suitable design some of it may be recovered and used. The effect of any such recovery is simply to increase the effective expansion ratio over the turbine by maintaining subatmospheric pressure at the turbine exhaust annulus. At an exhaust velocity corresponding to Mach number 0.6, the kinetic energy represents 70 deg F or 14 per cent of the total turbine power in a typical simple case. Recovery of one half of this would increase the net or useful output by some 20 per cent. In point of fact, an exhaust Mach number of 0.4 is more probable, and if so, the net gain to be achieved by recovery of one half of the kinetic energy is 10 per cent. In the design shown in Fig. 1 of the paper, space limitations may be severe, but recent aerodynamic developments have indicated how diffusion can be allowed on a bend, if the boundary layer is suitably controlled.

D. G. TRAVER.⁴ A few specific questions have come to mind on which we should like the author to comment. In Fig. 3 of the paper, the impulse-blading efficiency peaks within a point to two of the reaction blading. What are the conditions of this comparison? Our information indicates a somewhat larger difference. However, there are details which influence this consideration. Thus our comparison would be at the same Reynolds number and aspect ratio (ratio of blade length to axial width), and our Mach number would be sufficiently below 1 not to influence this comparison. In general, the author's curve substantiates ours in that we believe an impulse stage can be made which performs almost as well as a reaction stage. Frequently the mechanical advantages of the impulse stage counterbalance this small sacrifice in efficiency.

The popular classification of turbines into pure impulse and pure reaction types has almost lost its meaning to the gas-turbine designer, for he often deals with large-diameter-ratio blading in which three-dimensional effects are large, and in which there may be a radial variation in degree of reaction. Gas-turbine designers often depart from impulse or reaction conditions at the mean diameter even for small diameter ratios, for they may find a partial reaction stage better suited to their design requirements. There is no real justification for designing to the arbitrary limits of reaction or impulse stages, and it must be assumed that some sort of continuous efficiency envelope between these two types exists. Would the author indicate what form this envelope might take, and what he considers a "typical" impulse stage?

Referring to Fig. 7 of the paper, we use aspect ratio as a design parameter, and we would be interested in knowing the aspect ratios of these two curves. Our data for aspect ratio of 3 and Reynolds number = 100,000 (based on the throat hydraulic diameter as characteristic length) are the average of the author's curves over the entire range. Does Fig. 7 apply equally to impulse and reaction blading?

In Fig. 12 our findings are identical to the author's in the range of opening coefficients which we normally use in turbine design.

² Associate Professor of Mechanical Engineering, McGill University, Montreal, Can.

⁴ Research Engineer, Analytical Section, Elliott Company, Jeanette, Pa.

In regard to the author's discussion of aerodynamic loading and optimum pitch as developed by Zweifel, we use a variable optimum load coefficient that varies linearly with the reciprocal of aspect ratio, because the theory is developed for two-dimensional (infinite aspect ratio) flow conditions only. Our test data verify this variable load coefficient for normal reaction blading. However, our data do not agree, even in the two-dimensional case, with the optimum spacing indicated for impulse blades, but indicate a larger optimum pitch than calculated by Zweifel. This can be rationalized by assuming a more realistic ideal pressure distribution for impulse blades than the rectangular one assumed by Zweifel.

AUTHOR'S CLOSURE

Mr. Mordell points out the possibility of using diffusion to recover a portion of the residual kinetic energy from turbine-exhaust blading. The practicability of reducing leaving loss by this method is dependent upon the amount of kinetic energy available for recovery and upon space requirements for efficient diffusion. In multistage turbines of the general type shown in Fig. 1, the axial velocity of the gas leaving the last row of blades seldom exceeds 400 fps at rated load. Recovery of 50 per cent of the energy corresponding to this velocity would improve power-element efficiency about one per cent. However, power-element length would have to be increased over 25 per cent to provide an efficient diffusing turn for the exhaust gas. An increase in length of this magnitude is not practical for many installations, particularly for locomotive and marine service, in view of the small resultant gain in over-all efficiency.

With reference to Mr. Traver's questions concerning Fig. 3, the title is misleading in that the word "typical" applies to the curves rather than to the blading. Instead of identifying the stages as "reaction" and "impulse," it would be more proper to refer to them as "symmetrical" and "unsymmetrical." In both cases Reynolds number and aspect ratio are sufficiently high that their influences are small. The impulse or unsymmetrical staging has warped moving blades with a stage reaction at design conditions of zero at the root diameter and about 25 per cent at the mean diameter. The blading efficiency is somewhat better than that of a more conventional stage. The reaction or symmetrical blading is designed for 50 per cent reaction at all radii.

We have insufficient experimental evidence to plot, as suggested by Mr. Traver, a continuous efficiency envelope for blading varying in stage reaction from zero to 0.50. The shape of such a curve can be deduced to a certain extent from the following experimental results:

- 1 The efficiency of normal reaction blading is not affected by small unbalances in stage reaction above or below 0.50. The slope of the efficiency envelope curve must therefore be essentially zero at a stage reaction of 0.50.

- 2 The efficiency of a nominal impulse stage is generally improved by the introduction of a small amount of reaction, pro-

vided reasonable control over blade clearances is maintained to prevent gas leakage. The slope of the efficiency envelope curve must therefore be slightly positive for a stage reaction of zero.

We can probably assume from the foregoing that the efficiency envelope curve is roughly parabolic in form with a peak at a stage reaction of 0.50. However, the curve would be of academic interest only, as the internal configuration of any specific stage as regards blade height, diameter ratio, profile form, and operating clearance always exerts a major influence on its general efficiency level.

Concerning Mr. Traver's questions on Fig. 7, which shows expansion energy coefficient curves used in performance analysis, these data are assumed to apply to two-dimensional flow when the Reynolds number based upon throat-opening hydraulic diameter is 100,000 and higher. A value of 100,000 represents the lower limit of normal design practice, and over-all turbine tests seem to indicate only minor changes in efficiency as operating conditions are varied a moderate amount from this level.

Since the data in Fig. 7 apply only to two-dimensional flow, a gross stage power output calculated using these coefficients must be corrected for three-dimensional effects. The correction is made in terms of an end loss which includes clearance leakage, interference effects, and other secondary flow losses. The magnitude of the end loss is estimated from the blade height, blade profile, operating clearance, and clearance configuration. An aspect ratio such as defined by Mr. Traver (ratio of blade length to axial width) is not used as a design parameter.

The energy coefficients shown in Fig. 7 were determined by analyses of over-all turbine tests, and the curves may be considered to represent statistical averages. Individual tests show moderate variations above and below the curve values. The fact that wide blades generally show improved efficiency (provided the blades are of reasonable length) is believed to be due to two influences:

- 1 In practice it is seldom possible to maintain exact geometric similarity between wide and narrow blades. Trailing edge-wake loss generally increases as blading is narrowed, with a consequent slow decrease in over-all blade-energy coefficient.

- 2 Reynolds number effects have not been isolated satisfactorily in over-all turbine tests, but undoubtedly they are responsible for some reduced efficiency in narrow blades at moderate Reynolds number levels.

The data in Fig. 7 apply in general to both impulse and reaction blades. The expansion-energy coefficient of reaction blades or nozzles with very small outlet angles may fall slightly below the level of the curves. The kinetic-energy coefficient of impulse blades with very low deflection angles is generally somewhat higher than the expansion-energy coefficient as determined from Fig. 7. However, these types of elements are not normally employed in gas-turbine blade paths, so that the general accuracy of Fig. 7 is not affected for practical application.

Bending of an Ideal Plastic Metal¹

By J. D. LUBAHN² AND G. SACHS³

The stresses and strains in plastically bent parts have been analyzed for the two limiting conditions of (a) a very wide plate (plane strain), and (b) a very narrow bar (plane stress). The complete solution is presented for a hypothetical metal with no strain-hardening, and the method is described for treating any actual metal. The solution was obtained by a method of successive approximations, each approximation employing various graphical processes. The gradual change in cross-sectional contour with progressive bending was obtained by considering small successive intervals of increasing curvature. The final solution shows the movement of the neutral axis toward the compression surface, the decrease in the radial dimension of the part, and the gradual divergence between the tangential strains at the inside and outside surfaces. The solutions for plane stress and plane strain were nearly identical as regards the tangential strains and the changes in the radial dimension. Experimental measurements of surface strains and cross-sectional contour of bends conformed well with the results of the calculations.

NOMENCLATURE

The following nomenclature is used in the paper:

- A = angle subtended by a portion of the bend
- a = radius to concave surface of bent part
- a as a subscript refers to concave surface of bent part
- b = radius to convex surface of bent part
- b as a subscript refers to convex surface of bent part
- e = conventional strain
- F = component of force acting on an element of volume
- f as a subscript denotes final (strained) condition
- h = height or dimension in radial direction
- k = flow stress, i.e., uniaxial stress necessary to cause plastic flow
- L = element of length (tangential unless otherwise specified)
- m as a subscript denotes center (with respect to curvature, i.e., h_0/a) of a finite interval of bending
- n as a subscript denotes neutral axis, i.e., point of zero tangential stress or zero tangential strain differential
- r = radius to an arbitrary point
- r as a subscript denotes radial direction
- s = stress

t as a subscript denotes tangential direction (will be omitted where no ambiguity arises)

V = volume

w = breadth $[= w_0(1 + e_w)]$

w as a subscript denotes lateral direction

x = distance from an element of volume to concave surface ($= r - a$)

0 as a subscript denotes initial (unstrained) condition

1 as a subscript denotes direction of largest principal strain or stress

2 as a subscript denotes direction of intermediate principal strain or stress

3 as a subscript denotes direction of smallest principal strain or stress

ϵ = natural strain $[= \ln(1 + e)]$

$\bar{\epsilon}$ = uniaxial tensile strain causing an equivalent strain-hardening (when flow stress is a function of three principal strains)

' = beginning of finite interval of bending

" = end of finite interval of bending

INTRODUCTION

The bending of metal bars and plates by amounts sufficient to cause plastic deformation of practically the entire volume of the metal causes a condition of stress and strain throughout the part which is exceedingly complex. Under certain conditions, however, it is possible to treat the problem quantitatively, as discussed later, although the solution is involved and tedious. The simplifying conditions which are necessary to allow mathematical treatment of the problem are as follows: (a) It must be considered that the part is externally loaded only by end moments, i.e., that there is no pressure against the concave or convex surface, except at the ends of the bent portion; (b) the region of elastically deformed metal must be negligibly small; (c) all elements of volume of the part must have either zero lateral⁴ stress (condition of plane stress) or zero lateral strain (condition of plane strain); and (d) the bend must be long enough in the circumferential direction so that the end effects do not disturb the behavior of the metal near the center of the bend. These circumstances will be approached rather closely in bars which are sufficiently wide (approaching plane strain) or sufficiently narrow (approaching plane stress) and which contain a bend that is neither too mild nor too sharp.

Previous treatments (1, 2, 3, 4)⁵ of plastic bending have dealt with an even simpler set of circumstances where only the stresses and strains in the circumferential direction have been considered, the changes in cross-sectional contour have been neglected, and the effects of curvature on the position of the neutral axis have been disregarded.

In the present paper an "ideal plastic metal," i.e., one exhibiting no strain-hardening, will be assumed. Even with this assumption, however, the solution of the plastic-bending problem requires graphical methods for determining both the stresses and strains in a narrow bar and for determining the strains in a wide plate; only the stresses in a wide plate are obtainable algebraically. Consequently, for an actual metal with a specific stress-strain curve, the solutions would be but little more complex,

⁴ See Fig. 1 for definition of directions.

⁵ Numbers in parentheses refer to the Bibliography at the end of the paper.

as will be shown. On the other hand, the solutions for the ideal plastic metal conform closely to the deformation characteristics of real metals, so it appears that little is to be gained by repeating the procedure to be given for any real metals. This statement does not apply to the stresses, however, and consequently the bending loads, springback characteristics, and other aspects of bending require consideration of the strain-hardening and cannot be deduced accurately from the results of the present analysis.

PLASTIC-FLOW LAWS AND CONDITIONS OF THE PROBLEMS

In the following solutions of plastic-bending problems, the behavior of the metal will be considered to be governed by the following empirical relations,⁶ which are generally accepted as the "laws" of plastic flow:

(a) The condition that the volume remains constant during plastic flow can be expressed in terms of the principal natural strains by

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0 \dots \dots \dots [1a]$$

$$d\epsilon_1 + d\epsilon_2 + d\epsilon_3 = 0 \dots \dots \dots [1b]$$

where the natural strain ϵ , is defined in terms of the conventional strain e , or change in length divided by initial length, by

$$\epsilon = \ln(1 + e)$$

(b) The condition of stress under which plastic flow proceeds is given by the energy-of-distortion condition

$$(s_1 - s_2)^2 + (s_2 - s_3)^2 + (s_1 - s_3)^2 = 2k^2 \dots \dots \dots [2]$$

In this equation, k is the uniaxial stress necessary to cause plastic flow.

(c) The relation between the strains and stresses in the plastic state is given by

$$\frac{s_1 - s_2}{d\epsilon_1 - d\epsilon_2} = \frac{s_2 - s_3}{d\epsilon_2 - d\epsilon_3} = \frac{s_1 - s_3}{d\epsilon_1 - d\epsilon_3} \dots \dots \dots [3]$$

In addition to the foregoing relations governing the behavior of the metal itself, certain general principles of mechanics also apply to the situation at hand.

(d) For a stationary body, the equilibrium-of-force condition requires that the sum of the force components in any given direction (in particular, the radial direction) must be zero

$$\Sigma F_r = 0 \dots \dots \dots [4]$$

(e) For loading by end moments only, i.e., no external radial forces in the region considered, the equilibrium-of-force condition applied at the concave and convex surfaces of the bent part requires that the radial stresses at these surfaces be zero

$$s_r = 0 \text{ when } r = a \dots \dots \dots [5a]$$

$$s_r = 0 \text{ when } r = b \dots \dots \dots [5b]$$

SOLUTION FOR PLANE STRAIN

General Considerations. In the case of plane strain, the distribution of the stresses between initially unknown positions of the boundary surfaces can be determined algebraically. Subsequently, the position of the neutral axis can be determined, from which it is possible to calculate the strains and the height (see Fig. 1), and thus the positions of the concave and convex surfaces of the bent part.

If a wide plate is bent, the circumferential stretching at the convex surface tends to cause lateral contraction of this surface,

⁶ For a detailed discussion of these relations, see Nadai (1).

and similarly there is a tendency for the concave surface to expand laterally. This would cause lateral curvature of the part; but the resistance of the circumferentially curved plate prevents such lateral bending almost completely, and the lateral strains are therefore the same throughout the volume of the bend. Furthermore, the lateral resistance of the flat portions adjacent to the bend prevents any average lateral extension or contraction of the bend, so that the lateral strain ϵ_3 , is practically zero at every point.

FIG. 1 DEFINITIONS OF DIRECTIONS AND DIMENSIONS IN BENT PART

From considerations of symmetry it can be seen that the shear stresses are zero on planes determined by the radial, lateral, and circumferential directions, and consequently these are the principal directions. Because of the constant volume condition, the value zero for the lateral strain will require this to be the intermediate principal strain ϵ_3 , and the intermediate principal stress will be the lateral stress. Applying $\epsilon_3 = 0$ to Equations [3] and [1b] yields

$$s_2 = \frac{s_1 + s_3}{2} \dots \dots \dots [6]$$

Then Equation [2] becomes

$$s_1 - s_3 = \frac{2k}{\sqrt{3}} \dots \dots \dots [7]$$

Stress Distribution for Plane Strain. For rotational symmetry, equilibrium of force in the radial direction Equation [4] yields the following differential equation relating the radial and tangential stresses (5)

$$\frac{ds_r}{dr} = \frac{s_t - s_r}{r} \dots \dots \dots [8]$$

At the convex surface, s_t is a tensile stress and s_r is zero, so that s_t is the largest and s_r is the smallest principal stress. Then Equation [7] becomes

$$s_t - s_r = \frac{2k}{\sqrt{3}} \dots \dots \dots [9]$$

Combining this with Equation [8] and rearranging yields

$$\frac{ds_r}{k} = \frac{2dr}{r\sqrt{3}}$$

Integrating between the boundary condition [5b] and an arbitrary point r , s_r

$$\frac{s_r}{k} = \frac{2}{\sqrt{3}} \ln \frac{r}{b} \quad [10]$$

Equation [10] shows that s_r becomes negative as r becomes smaller than b and consequently, as r deviates from b , Equation [10] is applicable as long as s_r and s_t are continuous.

At the concave surface, s_t is a compressive stress and s_r is zero, so that s_t is the largest and s_r the smallest principal stress. Then Equation [7] becomes

$$s_r - s_t = \frac{2k}{\sqrt{3}} \quad [11]$$

which, combined with Equation [8] and integrating between the boundary Condition [5a] and an arbitrary point, r , s_r becomes

$$\frac{s_r}{k} = -\frac{2}{\sqrt{3}} \ln \frac{r}{a} \quad [12]$$

According to Equation [12], s_r becomes negative, as r becomes greater than a , and consequently, as r deviates from a , Equation [12] is applicable as long as s_r and s_t are continuous.

The solutions Equations [10] and [12] for s_r will be identical at one and only one value of the radius, so that Equation [10] will apply at larger radii and Equation [12] at smaller radii. Consequently this is the point where the tangential stress changes from positive⁷ to negative, and it will be designated as the neutral axis, r_n . The position of the neutral axis is obtained by setting equal to each other the two expressions Equations [10] and [12] for s_r , yielding

$$r_n = \sqrt{ab} \quad [13]$$

The distributions of radial stress in bends of various curvatures are shown in Fig. 2, in terms of the as yet unknown height, h . These curves show clearly the increase in radial compression as the curvature increases. The distribution of tangential and lateral stresses, as well as the radial stress, are shown in Fig. 3 for one particular value of the curvature of the bar, namely, for $h/a = 1$.⁸

The Neutral Axis. When $r < r_n$, the tangential stress is the smallest principal stress, as discussed previously, and consequently the principal direction in which the algebraically smallest change, de_t , in strain occurs is the tangential direction, i.e., $de_t = de_3$. Since $de_3 = 0$ and considering Equation [1b], de_3 must be negative. Thus de_t is also negative for $r < r_n$. Likewise, de_t is positive when $r > r_n$ because the tangential stress is the largest principal stress in this region. Consequently, de_t is zero at the neutral axis; and the neutral axis may be defined not only as the point of zero tangential stress, but also as the point of zero tangential strain differential. The variation with curvature of the neutral axis with respect to the as yet unknown positions of the bounding surfaces ($r = a$ and $r = b$) is shown in Fig. 4. The fact that $de_t = 0$ when $r_n = \sqrt{ab}$, together with the value of the curvature and the condition that the distribution of (conventional) tangential strain is linear across the radius,⁹ constitute the necessary information for determining the radial distribution of tangential strains.

⁷ For very large curvatures (small radii (a/h_0) of curvature, s_r according to Equations [9] and [10] may be negative at $r = r_n$, but the magnitude of the discontinuity in s_t at r_n will still be $4k/\sqrt{3}$ (compare [9] and [11]).

⁸ It is interesting to note that the stress distribution in a plastically bent plate is identical with that which would be obtained if one thick-walled tube were shrunk onto another in such a manner that both were in a condition of complete plastic flow (6).

⁹ It can be shown experimentally that the radial distribution of tangential strains is linear near the (tangential) center of even a rather sharp bend.

FIG. 2 DISTRIBUTION OF RADIAL STRESS IN BENDS OF VARIOUS CURVATURES FOR PLANE STRAIN

FIG. 3 RADIAL, TANGENTIAL, AND LATERAL STRESSES FOR PLANE STRAIN FOR $h/a = 1$

Strain Distribution. Because of the continuously changing position of the neutral axis with increasing curvature (see Fig. 4), the total tangential strain must be determined by integrating the differentials of strain occurring during small increments of bending in which the height remains constant and the neutral axis remains at a fixed distance ($r_n - a$) from the concave surface and the length L_n remains fixed, Fig. 5. Two cross sections bounding an initial length of the bar (before bending) of L_0 will subtend an

FIG. 4 CHANGE IN POSITION OF NEUTRAL AXIS DURING BENDING FOR PLANE STRAIN

FIG. 5 GEOMETRICAL CHANGES DURING AN INFINITESIMAL INTERVAL OF BENDING

angle, A , during the interval, and may be considered as rotating about the ends of the neutral axis during the interval. If the radius a , to the concave surface changes by da during the interval, the cross section at one end of the neutral axis will rotate through an angle dA , with respect to the cross section at the other end of the neutral axis, Fig. 5. The lengths, L_a and L_b of the fibers at the concave and convex surfaces, respectively, will change by small amounts, dL_a and dL_b , respectively. Fig. 5 yields two equations each for the lengths L_b and L_a , of the surface fibers

$$L_a = Aa \quad L_b = Ab = A(a+h) \dots \dots \dots [14]$$

and

$$dL_a = (a - r_n)dA = [a - \sqrt{a(a+h)}] dA \dots \dots [15]$$

$$dL_b = (a + h - r_n)dA = [a + h - \sqrt{a(a+h)}] dA \dots [16]$$

The constant volume condition, Fig. 6, yields the relation

$$\frac{h(L_a + L_b)}{2} = h_0 L_0 \dots \dots \dots [17]$$

Since by definition

$$1 + e_a = \frac{L_a}{L_0} \quad 1 + e_b = \frac{L_b}{L_0} \dots \dots \dots [18]$$

Equation [17] reduces to

$$\frac{h_0}{h} = 1 + \frac{1}{2}(e_a + e_b) \dots \dots \dots [19]$$

In order to determine the surface strains (e_a and e_b) after a change in curvature from zero to h/a , a method of successive approximations has been used consisting of the following steps:

1a Obtain a first approximation to the strains by assuming that the height remains constant and integrating Equations [15] and [16] algebraically.

1b Obtain a first approximation to h by using Equation [19] and the results of step 1a.

2a Using the values of h found by step 1b, integrate Equations [15] and [16] graphically to obtain a second approximation to the surface strains.

2b Determine a second approximation to h using Equation [19] and the results of step 2a.

The foregoing procedure yields successive approximations to the correct solution, each of which is more nearly correct than the preceding one. Consequently the procedure described under steps 2a and 2b may be repeated until the desired accuracy is obtained.

Step 1a. Considering h constant and differentiating Equation [14]

$$dL_a = daA + Ada$$

$$dL_b = dA(a+h) + Ada$$

By means of these relations and Equation [14], A can be eliminated from Equations [15] and [16], yielding

$$\frac{dL_a}{L_a} = \frac{da}{a} - \frac{da}{\sqrt{a(a+h)}} \dots \dots \dots [20]$$

$$\frac{dL_b}{L_b} = \frac{da}{a+h} - \frac{da}{\sqrt{a(a+h)}} \dots \dots \dots [21]$$

These equations can be integrated between the limits $L_a = L_b = L_0$ when $a = \infty$, and the general condition of strain, yielding

$$\frac{L_a}{L_0} = 1 + e_a = \frac{4a}{2a + h + 2\sqrt{a(a+h)}} \dots \dots [22]$$

FIG. 6 CONSTANT VOLUME CONDITION FOR PORTION OF BENT SHEET

$$\frac{L_b}{L_0} = 1 + e_b = \frac{4(a+h)}{2a+h+2\sqrt{a(a+h)}} \dots [23]$$

These values of e_a and e_b are shown in Fig. 7, curve 1 (to designate the first approximation).

FIG. 7 SUCCESSIVE APPROXIMATIONS TO EXTREME TANGENTIAL STRAINS FOR PLANE STRAIN

FIG. 8 SUCCESSIVE APPROXIMATIONS TO CHANGE IN HEIGHT ON BENDING FOR PLANE STRAIN

Step 1b. Using the surface strains given by Equations [22] and [23], the height (expressed as a fraction of the initial height) can be determined from Equation [19]. This is plotted in Fig. 8, curve 1 (to designate the first approximation).

Step 2a. For graphical integration of Equations [15] and [16], these equations may be applied to a small finite interval of

bending whose beginning is designated by prime, and whose end is designated by double prime. If the interval is sufficiently small, h and $(r_a - a)$ may be considered as constant during the interval and may be taken at a curvature midway (subscript m) between that at the beginning and that at the end of the interval. Then Equations [15] and [16] become

$$L''_a - L'_a = (A'' - A') (a_m - r_{nm}) \dots [24]$$

$$L''_b - L'_b = (A'' - A') (a_m + h_m - r_{nm}) \dots [25]$$

where

$$r_{nm} = \sqrt{a_m(a_m + h_m)}$$

Applying Equation [14] to the beginning and end of the interval yields values of A' and A'' which can be substituted into Equations [24] and [25] yielding

$$\frac{L''_a}{L'_a} = \left(\frac{a''}{a'} \right) \frac{a' - a_m + r_{nm}}{a'' - a_m + r_{nm}} \dots [26]$$

$$\frac{L''_b}{L'_b} = \left(\frac{a'' + h''}{a' + h'} \right) \left(\frac{a' - a_m + r_{nm}}{a'' - a_m + r_{nm}} \right) \dots [27]$$

Dividing numerator and denominator of the left member by L_0 and of the right member by h_0 yields the strains at the end of the interval in terms of the strains at the beginning of the interval and quantities available from the previous approximation

$$\left(\frac{L''_a/L_0}{L'_a/L_0} \right) = \frac{1 + e''_a}{1 + e'_a} = \left(\frac{a''/h_0}{a'/h_0} \right) \left(\frac{a'/h_0 - a_m/h_0 + r_{nm}/h_0}{a''/h_0 - a_m/h_0 + r_{nm}/h_0} \right) \dots [28]$$

$$\left(\frac{L''_b/L_0}{L'_b/L_0} \right) = \frac{1 + e''_b}{1 + e'_b} = \left(\frac{a''/h_0 + h''/h_0}{a'/h_0 + h'/h_0} \right) \times \left(\frac{a'/h_0 - a_m/h_0 + r_{nm}/h_0}{a''/h_0 - a_m/h_0 + r_{nm}/h_0} \right) \dots [29]$$

Values of h/h_0 at a'/h_0 , a_m/h_0 , and a''/h_0 , respectively, are given in Fig. 8, curve 1. The fact that intervals of h_0/a of one half are sufficiently small to give good accuracy can be shown by comparing the results of Equations [28] and [29] for this interval size and for a constant value of h , ($h = h_0$), with the results of Equations [22] and [23], respectively. The second approximation to the surface strains obtained by Equations [28] and [29] is shown in Fig. 7, curve 2.

Step 2b. Using the surface strains given in Fig. 7, curve 2, a second approximation to the height can be determined from Equation [19]. This is shown in Fig. 8, curve 2.

The third and fourth approximations (curves 3 and 4 in Figs. 7 and 8) show that consecutive solutions yield values approximately midway between those of the two preceding solutions. This information makes it possible to make an estimate directly of the final solution, which may be verified by applying steps 2a and 2b of the foregoing procedure to the estimate. The result, Fig. 9, shows that the estimate based upon four approximations is quite accurate.

The final solution for the surface strains is shown in Fig. 10 where the results are compared with the "conventional bending strains," i.e., those obtained by assuming constant height and that the neutral axis remains at the center of the height.

As will be shown, the tangential surface strains are the same for plane stress as for plane strain (within the limits of accuracy of the method); and in Fig. 10 are presented some data for various conditions between these limits, which show that the theoretical solutions agree closely with experimental measurements for bars or plates of any width. Of particular significance is the fact that

FIG. 9 HEIGHT CHANGE DURING BENDING FOR PLANE STRAIN ACCORDING TO LAST APPROXIMATION AND FINAL SOLUTION

FIG. 10 COMPARISON OF MEASURED AND THEORETICAL CIRCUMFERENTIAL SURFACE STRAINS FOR WIDE RANGE OF W_0/h_0 VALUES BETWEEN PLANE STRAIN AND PLANE STRESS

the agreement is good between the theoretical solution for an ideal plastic metal and data for an actual metal. This means that the strain-hardening characteristics of the metal have but little influence on the strains in bending and consequently the foregoing solution should be applicable to a wide variety of metals, in so far as the strains are concerned. However, the stresses will vary considerably from metal to metal.

SOLUTION FOR PLANE STRESS

Development of Equations for the Stresses. A sufficiently thin

strip which is bent edgewise, Fig. 11, will have zero stress in the lateral direction (i.e., $s_w = 0$), and thus will be in a state of "plane stress." Since the radial stress is zero at the convex and concave surfaces, these surface fibers will be in a state of uniaxial tension and uniaxial compression, respectively, in the tangential direction, i.e.

$$\left. \begin{aligned} s_t &= s_l = k \text{ when } r = b \\ s_t &= s_l = -k \text{ when } r = a \end{aligned} \right\} \dots \dots \dots [30]$$

and

Under conditions of uniaxial tension and compression there are lateral contraction and expansion, respectively, causing the cross section to distort into a figure resembling a trapezoid, Fig. 11. Out of a bar with such a cross section, an element of volume having infinitesimal dimensions in the radial and tangential directions but the full breadth, w , of the bar in the lateral direction will have acting upon it the forces shown in Fig. 11. The sum

FIG. 11 FORCE ACTING ON AN ELEMENT OF VOLUME IN BENT BAR; PLANE STRESS

of the force components in the radial direction may be equated to zero, yielding

$$(s_r + ds_r)(w + dw)(r + dr)d\theta - s_r w d\theta - 2s_t dr (w + dw) \sin \frac{d\theta}{2} = 0 \dots \dots [31]$$

where $d\theta$ is an infinitesimal angle between the two radial planes which bound the element. Equation [31] reduces to

$$\frac{ds_r}{dr} = \frac{s_t - s_r}{r} - \frac{s_r dw}{w dr} = \frac{s_t - s_r}{r} - \frac{s_t de_w}{(1 + e_w) dr} \dots \dots [32]$$

To solve this equation, it is necessary to reduce the number of variables to two, namely, the independent variable r , and one dependent variable. This requires that e_w be known as a function of r and that there be a relation between s_t and s_r . The latter relation is furnished by combining Equation [2] with the condition of plane stress ($s_w = 0$), yielding

$$s_t = \frac{s_r \pm \sqrt{4k^2 - 3s_r^2}}{2} \dots \dots \dots [33]$$

Consideration of Equation [30] shows that the choice of sign in Equation [33] should be negative when $r = a$, and positive when $r = b$.

Procedure for Numerical Solution. The relation necessary for the solution of Equation [32], giving w as a function of r , i.e., the radial distribution of lateral strains in the bent part, is a complex function (see Equation [3]) of the stresses which in turn require for their determination the solution of Equation

[32]. Thus, at the best, an algebraic solution for Equation [32] would be very complex, and even then not adaptable to the solution for an actual (strain-hardenable) metal. Consequently a solution was obtained by a method of successive approximations, each approximation consisting of the steps shown in Table I, and resulting in a more accurate set of cross sections than the previous set. The final result of any one approximation must be expressed as a set of cross sections, rather than a single one, to represent the increasing "sharpness" of the bend, as expressed by the curvature, h_0/a , of the concave surface.

TABLE I OUTLINE OF STEPS FOR ONE APPROXIMATION

- For the first approximation, assume some arbitrary (but reasonable) set of cross sections which vary in shape with progressive bending. For all succeeding approximations, use the set of cross sections determined by the previous approximation.
- Using cross sections given by (a), solve Equation [32] for stresses.
- Determine position of neutral axis as point of zero tangential stress.
- Using this position of neutral axis and assumed condition of linearly distributed tangential strains, calculate extreme tangential strains.
- Determine lateral and radial strains.
- Integrate radial strains to obtain height. This, together with distribution of lateral strains, is necessary information for integrating Equation [32], which is first step of next approximation.

The results of the analysis¹⁰ show that the method of successive approximations as outlined is a converging process, i.e., each successive result is closer to a self-consistent final solution than the previous one. The method may be repeated as many times as necessary to obtain the desired accuracy, i.e., until the last and second last set of cross sections differ by less than the accuracy of experimental work.

Stress and Strain Distributions. The distributions of radial and tangential stress across the (initially unknown) height are shown in Figs. 12 and 13, respectively, for several curvatures, as

FIG. 12 VARIATION OF RADIAL STRESSES WITH PROGRESSIVE BENDING FOR PLANE STRESS; FIRST APPROXIMATION

calculated by the steps leading to the first approximation. Succeeding approximations yielded similar stress distributions.

The change in position of the neutral axis with changing curvature, Fig. 14, is nearly the same as for plane strain, Fig. 4. The neutral axis remains slightly closer to the center line in plane stress than in plane strain.

¹⁰ The detailed mathematical procedure of this analysis can be found in Report No. M-478 of the National Defense Research Committee of the Office of Scientific Research and Development entitled "Correlation of Information Available on the Fabrication of Aluminum Alloys (NA-126): Section V—Formability of Aluminum Alloys for Use in Military Aircraft, Part IV—Fundamentals of Pure Bending of an Ideal Plastic Metal Under Conditions of Plane Stress," by G. Sachs, J. D. Lubahn, and J. M. Taub, April 26, 1945.

FIG. 13 VARIATION OF TANGENTIAL STRESSES WITH PROGRESSIVE BENDING FOR PLANE STRESS; FIRST APPROXIMATION

FIG. 14 SHIFT OF NEUTRAL AXIS FOR PLANE STRESS EXPRESSED AS FRACTION OF FINAL HEIGHT; FINAL SOLUTION

FIG. 15 VARIATION OF HEIGHT FOR PLANE STRESS FOR ESTIMATED AND FINAL SOLUTIONS

The height (the solid curve in Fig. 15) decreases with increasing curvature in almost the same manner as in plane strain (Fig. 9, solid curve). The change in height is slightly less for plane stress than for plane strain.

The tangential strains at the concave and convex surfaces are practically identical with those obtained for plane strain, and may be taken with sufficient accuracy directly from the solid curve in Fig. 10. The conditions of plane stress and plane strain represent the extremes of zero and infinity for the breadth-to-height ratio of curved parts. The identical results obtained for the tangential surface strains for these extremes suggest that these surface strains might apply to bars of all intermediate breadths. Fig. 10 shows data for bars having breadth to height ratios between 0.5 and 5.5. These results all agree within the experimental error with the theoretical strains for plane stress or plane strain.

The shape of the cross section can be expressed by the distribution of lateral strains across the height. The variation of these strains with increasing curvature is shown by the solid lines in Fig. 16. It is interesting to note that the breadth of the part increases slowly from the tension side to the center, and then more rapidly as the compression side is approached. Fig. 17 shows the radial distribution of lateral strain for a curvature (h_0/a) of 1.3, according to the theoretical solution for plane stress. A condi-

FIG. 16 VARIATION OF LATERAL STRAINS FOR PLANE STRESS FOR ESTIMATED AND FINAL SOLUTIONS

FIG. 17 MEASURED RADIAL DISTRIBUTION OF LATERAL STRAIN FOR $W_0/h_0 = 0.1$ AND THEORETICAL DISTRIBUTION FOR PLANE STRESS

tion of plane stress exists in a hypothetical bar whose breadth-to-height ratio is zero. An actual specimen with a very small breadth-to-height ratio (0.1) yielded a radial distribution of lateral strain very nearly that predicted by the theory for plane stress (for the same curvature), Fig. 17. This agreement not only bears out the theoretical analysis, but also indicates that a rather thin strip bent edgewise corresponds closely to a condition of plane stress.

History and Performance of the Oil-Refinery Steam-Electric Generating Stations of the Pacific Gas and Electric Company

By V. F. ESTCOURT,¹ SAN FRANCISCO, CALIF.

Design and operating characteristics are given for the three 1400-psi 940 F steam-electric generating stations built by the Pacific Gas and Electric Company for furnishing process steam and electricity to the three adjacent oil refineries, in addition to generating firm power for its own transmission system. An analysis is made of a number of special problems peculiar to this sort of undertaking, and both the advantages and limitations are discussed and evaluated, with emphasis upon the factors which must be considered in order to gain the maximum benefits from such a joint venture. It is pointed out that this type of plant can deliver the refinery's variable requirements for process steam without materially affecting the ability to generate firm power at high thermal efficiencies. However, high-sulphur fuels require higher exit-gas temperatures in order to avoid air-preheater corrosion, with resultant lower boiler efficiencies.

JOINT studies were conducted in 1937, in conjunction with the Tidewater-Associated, Shell, and Union Oil Companies for the purpose of working out the design details and contractual arrangements whereby the Pacific Gas and Electric Company would construct steam-electric generating stations respectively adjacent to the oil refineries of these three oil companies for the generation of electric power and process steam for the use of the refineries, plus electric power for the transmission system of the Pacific Gas and Electric Company. The three contracts as finally written were almost identical except for certain minor provisions relating to the fuels to be burned and the quantities of steam and power to be delivered to the refineries.

The first of these plants, located at Avon, Calif., adjacent to the Tidewater-Associated Company's oil refinery, was placed in operation on December 15, 1940; the second plant, located at Martinez adjacent to the Shell Oil Company's refinery, went into service on June 13, 1941; and the Oleum Plant, adjacent to the Union Oil Company's refinery, first went on the line on January 15, 1942. A second identical unit was installed at Oleum and placed in service on May 24, 1943. This unit was solely for the purpose of meeting the load growth on the Pacific Gas and Electric system.

A detailed description of the design of these stations already has been published in a paper by C. E. Steinbeck.² In that paper was included a plan of the station layout, a cross section of

the boilers and turbines, and a flow diagram showing both the conventional plant cycle and the superimposed process cycle for the generation of steam for the neighboring oil refineries. Mr. Steinbeck's paper was written before any of the plants had been placed in operation and therefore was confined to a description of the basic layout. This present paper may be considered as a continuation of the subject from the point where Mr. Steinbeck's discussion ended.

FUNDAMENTAL CONSIDERATIONS

There are certain fundamental considerations which must be taken into account before it is possible to write a contract which will be satisfactory to both parties on a long-term basis. The refinery, on the one hand, expects to get a cheaper and more reliable source of steam and electric power. On the other hand, if the undertaking is to be attractive to the utility, it must be possible to design the installation so that this sort of service can be given to the refinery at an over-all cost to the utility which is competitive with the cost of generating electric power in its conventional generating stations. This calls for a very careful and realistic analysis in order to avoid overlooking factors which might later prove to be detrimental to either party, or which might result in making commitments which cannot be met in practice, thereby disturbing the balance of the mutual advantages which rightfully can be anticipated in a carefully worked out agreement.

The plant must also be designed not only to meet the existing steam and electric requirements of the oil refinery but must be capable of reasonable expansion in anticipation of future growth not only of the oil refinery but also of the electric facilities of the utility. This may not be easy to do without sacrificing some of the original advantages unless the problem is given detailed consideration in the initial design.

The basic advantages which may be gained by the parties in entering into such an arrangement are as follows:

(a) The combined project, if properly conceived, will result in over-all economies which cannot be realized by either party separately. If the various technical and commercial factors are given realistic consideration, the resultant benefits can and should be shared equally by both parties.

(b) The oil refinery is provided with a reliable source of low-cost electrical energy and process steam.

(c) The oil refinery is provided with a commercial outlet for its waste fuels, and the burning of such fuels for the generation of electric energy is a contribution in the interests of conservation of our natural resources.

(d) In addition to the sale of electricity and steam to the oil refinery, an appreciable block of electrical energy with firm power value can be delivered to the transmission system of the utility.

(e) A stable source of fuel supply is made available to the utility not only to meet the refinery requirements, but also for the generation of the energy which is delivered into the utility's transmission system.

Contributed by the Power Division and presented at the Semi-Annual Meeting, San Francisco, Calif., June 27-30, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-SA-11.

PRINCIPAL FEATURES OF THE CONTRACT

The three contracts were signed during 1937 and 1938, and received the approval of what was then known as the California State Railroad Commission but which now functions under the name of California Public Utilities Commission. The maximum steam and electric quantities involved in each case are given in Table 1.

TABLE 1 STEAM AND ELECTRIC REQUIREMENTS OF REFINERIES

Name of company	Process steam, lb per hr	Electricity, kw
Tidewater-Associated Oil Company....	275000	15000
Shell Oil Company.....	325000	15000
Union Oil Company.....	275000	15000

The Pacific Gas and Electric Company agreed to furnish process steam and electric energy in quantities not to exceed the maximum demands given in Table 1, in exchange for certain quantities of "substitute fuels," plus cash payments based upon a demand charge plus a commodity charge. A formula was established wherein the barrels of substitute fuel to be delivered by the oil companies in part payment for the steam and electricity was obtained by multiplying by a certain factor the total pounds of steam or kilowatt-hours delivered to the refinery. There are different multiplying factors for steam and electricity, respectively.

The definition of substitute fuel, as applied in the contract is "any liquid or gaseous fuel, including refinery-waste fuel such as acid sludge, tars, waxes, and gases which will not leave an unburnable residue in excess of 2 per cent by weight, and will produce substantially the same output of steam from the boilers as when fired to capacity with fuel oil." In addition to the foregoing, a further provision was made at the Oleum Steam Plant to include pulverized petroleum coke having the following analysis:

Volatile constituents.....	not less than 10 per cent
Fixed carbon.....	not more than 90 per cent
Ash.....	not more than 1 per cent
Sulphur.....	not more than 2 per cent
Impregnated oil.....	not more than 2 per cent

Provision was also made for the purchase by the Pacific Gas & Electric Company of certain quantities of "excess fuel oil" over and above the amounts delivered to it in payment for steam and electricity. This feature provided a firm source of fuel supply for the generation of electric power for the company's own transmission system. In Fig. 1 is given a diagrammatic representation of the disposition of the various quantities of steam, electricity, fuel, and cash involved in the operation of the contract. Based upon a nominal maximum load of 46,000 kw, more than 30,000 kw is delivered to the company's transmission system, and a little under 12,000 kw is delivered to the oil refinery, plus

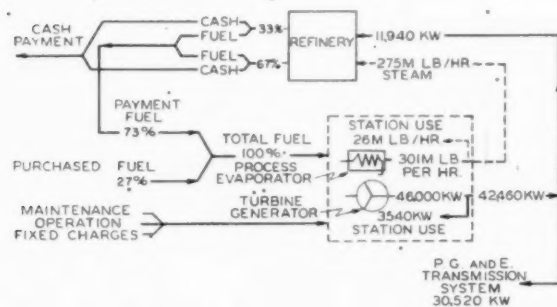

FIG. 1 DISTRIBUTION OF STEAM AND ELECTRIC LOADS, CASH AND FUEL PAYMENTS, ETC., AVON STEAM PLANT

275,000 lb per hr of process steam. Of the total payment in terms of fuel and cash for these quantities of steam and electricity, 67 per cent is for steam and 33 per cent is for electric energy. Under the operating conditions shown in the diagram, the total payment fuel represents 73 per cent of the total fuel requirements of the station, and the remaining 27 per cent must be purchased under the excess-fuel-oil clause in the contract.

DESIGN AND OPERATING CHARACTERISTICS

In order to meet the operating requirements of the Pacific Gas and Electric system, the turbine generators had to be capable of providing a firm electrical power source for its own system without being dependent upon the process-steam demands of the oil refinery. It was also necessary to make the installation self-sufficient as an electric generating station even though the contract with the oil refinery were discontinued at some future date. From this point of view, a straight back-pressure turbine presented distinct disadvantages, because in this case there must be an outlet for the exhaust steam before the turbine is able to generate power. Therefore, single 50,000-kw, 3600-rpm tandem-compound units with automatic extraction at the exhaust of the high-pressure turbine were selected for each of the three stations, and are designed for an initial steam pressure of 1400 psig and a total steam temperature of 940 F. Although these units are nominally rated at 50,000 kw, they have under favorable extraction conditions operated as high as 55,000 kw. Their average capability under the usual refinery steam loads is about 46,000 kw.

The turbine is designed so that it may be operated either as a straight condensing tandem-compound machine or as an automatic extraction unit. It is only on rare occasions that it is necessary to operate on a straight condensing basis; and, under these conditions, the capacity of the unit is reduced to approximately 41,000 kw. Thus, should the oil refinery temporarily curtail or discontinue taking process steam, as was the case during the recent Pacific Coast oil-refinery strike, the plant is able to continue generating more than 80 per cent of its nominal capacity. Should the refinery permanently discontinue taking process steam, it would be feasible to add a second low-pressure condensing element of approximately 25,000 kw capacity, thereby raising the nonextraction capacity of the unit from 41,000 to 66,000 kw with the same installed boiler capacity.

The low-pressure turbine exhausts into a condenser which is somewhat smaller than would be used for a conventional condensing machine for the reason that large quantities of steam normally are extracted at the exhaust of the high-pressure element, thus unloading the condenser. This feature is illustrated by the curve in Fig. 2 showing that at 40,000 kw and with a contract demand of 275,000 lb per hr of process steam, the flow to the condenser is only 172,000 lb per hr, as compared with 324,000 lb per hr for straight condensing operation; or stating it in another way, the condenser flow for these conditions, when operating on an automatic extraction basis, is approximately 53 per cent of what it would be for straight condensing operation. Obviously, any reduction in condenser losses with the same kilowatt output results in a substantial gain in economy in the over-all cycle, as well as a saving in initial investment for the smaller condenser. Due to the relatively few hours of operation on a straight condensing basis, it is economical to overrate the condenser for these conditions at some sacrifice in efficiency.

There is a somewhat complicated relationship between the electric generating capability of the turbine generator and the process-steam flow to the oil refinery. From the curves in Fig. 3 it can be seen that, as the refinery steam load increases, the electric load on the turbine generator can be held constant or increased until the control valves on the low-pressure turbine are wide open. When this optimum point is reached, any further in-

crease in the electric load can be made only by increasing the refinery steam load. In this connection it is interesting to note that the second unit installed at Oleum made it possible to divide the extraction load between the two units and thereby operate more nearly at this optimum extraction point, so that the capability of the first machine was slightly increased as a direct result of installing the second unit. At a refinery steam demand of 275,000 lb per hr and with all of the extraction steam coming from one machine, the capacity of the turbine is 46,000 kw, as compared with 48,000 kw on each of two units with the extraction divided equally between them.

The steam which is extracted from the high-pressure turbine is passed through the process evaporator coils, and the condensate is returned to the plant cycle. The heat exchange with the process feedwater results in the generation of steam at approximately

FIG. 2 STEAM FLOW TO CONDENSER FOR DIFFERENT GENERATOR LOADS UNDER BOTH STRAIGHT CONDENSING AND EXTRACTION OPERATION OF 50,000-KW TURBINE-GENERATOR AT AVON STEAM PLANT

FIG. 3 OPERATING CHARACTERISTICS OF 50,000-KW TURBINE GENERATOR AT AVON STEAM PLANT FOR VARIOUS ELECTRIC AND EXTRACTION LOAD CONDITIONS

165 psig. The evaporators were selected for a moderate temperature head which varies both with the process steam load and the cleanliness of the evaporator coils. The extraction pressure is controlled by a feeler line connected to the 165-psig steam pipe to the oil refinery. Thus, although the nominal extraction pressure at the exhaust of the high-pressure turbine has been referred to as 240 psig, actually this pressure varies automatically with the evaporator load as indicated in Fig. 4. This serves to hold the temperature head at a minimum, thereby reducing the inherent loss in cycle efficiency where a heat exchanger is interposed, in order to recover as condensate the steam extracted from the high-pressure turbine.

FIG. 4 PROCESS-EVAPORATOR OPERATING CHARACTERISTICS AT DIFFERENT OUTPUTS—AVON STEAM PLANT

In view of the foregoing, the losses resulting from the use of a closed cycle are not as great as sometimes have been indicated. The only other alternative is to deliver the extracted steam from the exhaust of the high-pressure turbine directly to the oil refinery. This immediately introduces a major problem in controlling the chemical content of large quantities of raw make-up water which must be fed to the high-pressure boilers. It is usually difficult to obtain condensate returns from the oil refinery which are free enough from oil contamination for satisfactory high-pressure boiler feedwater. Therefore the added investment cost in water-conditioning equipment plus increased operating and maintenance costs will in some instances offset the theoretical gain in cycle efficiency.

In electric systems such as ours, where an appreciable percentage of the power output is generated from hydroelectric sources, there sometimes occur seasonal conditions wherein all or at least a considerable number of the steam plants must be operated at minimum load in order to prevent loss of water over the dams during periods of high run-off. As indicated in Fig. 5, the amount of process steam required by the refinery determines the minimum electric load which can be carried by the turbine generator when operating on a strictly automatic extraction cycle. This minimum occurs when the low-pressure-turbine control valves are closed so that the high-pressure turbine is functioning as a straight back-pressure machine with its load fixed by the amount of extraction steam being delivered to the evaporator coils. In order to reduce the load below this minimum, it is necessary to by-pass a portion of the steam requirements for the process evaporators around the turbine and through the reducing valves which are provided primarily for occasions when the turbine is shut down for overhaul. Obviously, there is considerable loss in efficiency when

FIG. 5 MINIMUM POSSIBLE LOADS ON 50,000-KW TURBINE GENERATOR FOR VARIOUS REFINERY STEAM LOADS WHEN OPERATING ON AUTOMATIC EXTRACTION—AVON STEAM PLANT

all or part of the steam supply for the evaporators is passed through the reducing valves, and these factors must be evaluated in determining the average cost of steam and electric energy supplied to the oil refinery. On many power systems it may be feasible never to operate below the minimum load possible with full-automatic extraction, and therefore the only time when it will be necessary to use the reducing valves will be for the short periods during which the turbine is shut down for overhaul.

One of the problems requiring special consideration is the size and number of boilers. Due to the burning of waste fuels the boiler availability is somewhat less than is possible with good commercial fuels, and furthermore, the oil refinery cannot be expected to curtail or shut down its plant in order to permit the utility to carry on routine maintenance. Therefore special consideration must be given to this problem in the boiler layout. As indicated by the curve in Fig. 6, there are three boilers per turbine, each having a continuous rated capacity of 200,000 lb of steam per hr and an overload capacity of 230,000 lb per hr. It is of interest

FIG. 6 BOILER STEAM-FLOW REQUIREMENTS FOR VARIOUS TURBINE-GENERATOR LOADS AND A REFINERY STEAM LOAD OF 275,000 LB PER HR

to note that, due to the base load which must be carried by the boilers in order to meet the demand for process steam, the loss of one boiler, representing one third of the total boiler capacity, results in an electric-load reduction of more than 50 per cent. Thus it is clear that it is desirable not only to carry some additional reserve boiler capacity in order to offset the slightly lower boiler availabilities with waste fuels, but it is also necessary to install several small boilers rather than a lesser number of large boilers, in order to avoid an excessive load reduction on the turbine generator when one boiler is out of service.

HEAT RATE FOR ELECTRIC GENERATION

In Fig. 7 the estimated heat rate per kilowatthour of electric generation has been plotted as a separate item by segregating the proportions of fuel chargeable, respectively, to the generation of process steam and electricity. There are various methods of com-

FIG. 7 HEAT RATE IN BTU PER KW-HR OF ELECTRIC GENERATION AFTER DEDUCTING FUEL REQUIRED FOR GENERATION OF 275,000 LB PER HR OF PROCESS STEAM—AVON STEAM PLANT

puting the proper allocation based upon the initial premises which are set up; but for the purpose of establishing the curve in Fig. 7 it was decided to credit the total fuel consumption for both process steam and electricity with the amount of fuel that would be required to generate the contract demand for 275,000 lb per hr of process steam in low-pressure boilers. Then the balance of the total fuel used is all that is chargeable against electric generation. It is fully realized that this method of allocating the fuel for process steam and power is debatable, but a study of other methods of arriving at a solution based upon a breakdown of the various components of the plant cycle led to the conclusion that these also left much to be desired and involved more complication than appeared to be justified for the present objective.

BURNING OF WASTE FUELS

The physical and chemical characteristics of refinery-waste fuels are subject to considerable change from time to time, and the fuel-burning equipment at the plant must be sufficiently flexible to anticipate such changes. The design of the boiler must also be such that fuels which are high in ash and sulphur may be burned with reasonable boiler availability. Some of these liquid-petroleum-base fuels present operating difficulties which are not

usually encountered with coal. Therefore the commercial aspects of the contract must be worked out properly so that the extra handling and maintenance costs plus lower boiler availability associated with certain of these waste fuels will not penalize the utility in the cost of electric generation.

The types of fuels burned differ somewhat in each of the three plants under consideration; and from time to time there have also been radical changes both in the type and quality of the fuels delivered to any particular plant due to the changes in the manufacturing programs at the respective refineries. To date the types of fuels which have been burned are given in Table 2. The analyses of these fuels are given in Table 3.

TABLE 2 TYPES OF FUELS BURNED

Avon	Martinez	Oleum
Acid sludge	Recovered oil	Pulverized petroleum coke
Pitch	Cracked asphalt	High-sulphur fuel oil
Heavy fuel oil	Heavy fuel oil	Commercial fuel oil
High-sulphur fuel oil	High-sulphur fuel oil	Natural gas
Commercial fuel oil	Commercial fuel oil	
Natural gas	Natural gas	

TABLE 3 TYPICAL ANALYSES OF CRITICAL FUELS

	Per cent by weight	
	Sulphur	Ash
Acid sludge	2.9-4.6	0.03-0.06
Recovered oil	6.0-9.0	0.01-0.09
Pitch	0.05	0.70
High-sulphur fuel oil	3.0-4.6	0.08-0.14
High-sulphur petroleum coke	4.0-4.2	0.51-0.84

The curves in Fig. 8 show historically the types and quantities of each kind of fuel which have been burned at the Avon plant since it was started up in December, 1940. It is interesting to note that during the war years, large quantities of natural gas were burned as a result of a co-operative effort between the Pacific Gas and Electric Company and the oil refineries on the one hand, and the United States Navy on the other hand, in order to make the maximum amount of fuel oil available for the Navy. Again, during the months of September, October, and November, 1948, it became necessary to burn natural gas in order to keep our plants in operation during the Pacific Coast oil-refinery strike.

Our early experience with the burning of acid sludge resulted in rather low boiler availability owing to external fouling of the boiler heating surfaces; and because of combustion instability, supporting gas or oil pilot fires must be used. However, as a result of research on the part of the oil company, changes were made in its equipment and processes so that the modified acid sludge could be burned with fairly high boiler availability. Due to the high water content, it must not be heated much above 190 F in order to avoid a boilover in the heated storage tanks, and this temperature is satisfactory at the burners.

The problem of burning pitch or cracked asphalt is confined merely to maintaining its temperature at the burners at approximately 400 F in order to obtain a satisfactory viscosity for burning it under the boilers. At ordinary temperatures it is in the solid state, and therefore considerable care must be exercised in seeing that the temperature of this material is never allowed to go too low. This is accomplished by means of steam tracer lines bound to the fuel lines and surrounded by insulation. Other than this, it has proved to be a fairly acceptable fuel which can be burned almost as satisfactorily as the commercial grade of fuel oil derived from the same crude, although it is somewhat higher in ash content and therefore will produce slightly more deposits on the boiler heating surfaces than will the fuel oil.

So-called "recovered oil" is the end product after extracting a large percentage of the sulphuric acid present in acid sludges resulting from the manufacture of lubricating oil. Both acid sludge and recovered oil are highly corrosive, and the products of combustion are very corrosive at temperatures which normally would

FIG. 8 HISTORICAL CHART SHOWING PROCESS STEAM AND ELECTRIC ENERGY DELIVERED TO OIL REFINERY, AND TYPES OF FUEL BURNED AT AVON STEAM PLANT

exist in the air preheater of the boiler. All fuels with high sulphur contents such as acid sludge, recovered oil, high-sulphur fuel oil or coke, and the like, make it necessary to provide for partly by-passing the air preheater so that the exit-gas temperature can be held above the dew point. The effect of the presence of sulphur, or rather of sulphur trioxide, upon the dew point of the exit gases is fairly well understood, and it is necessary, in order to avoid air preheater corrosion, to maintain these temperatures in general conformity with the curves shown in Fig. 9 as the sulphur content in the fuel increases. This results in an appreciable reduction in boiler efficiency which should be taken into account in working out the commercial details of the contract.

HIGH-SULPHUR FUEL OILS AND PETROLEUM COKE

Certain so-called high-sulphur fuel oils and petroleum cokes require special consideration in order to be able to burn them with reasonable boiler availability and maintenance costs. The particular fuel oil referred to here has the sulphur and ash contents shown in Table 3. The degree of external fouling of the boiler heating surfaces appears to be influenced by the combination of both the high sulphur and ash contents. It is not felt that the presence of high sulphur by itself would result in appreciable fouling, but it also has been fairly well demonstrated that, in the presence of a high ash content, the combination will produce a bad fouling problem. In certain temperature zones, a binding action exists which results in maximum deposits on the heating surfaces

FIG. 9 MINIMUM SAFE FLUE-GAS TEMPERATURES FOR VARIOUS PERCENTAGES OF SULPHUR IN FUEL OIL IN ORDER TO AVOID AIR-PREHEATER CORROSION

in that area. The mechanism by which deposits are formed on a heating surface has to do primarily with the fusion and softening points of the ash. Deposits will occur largely in those parts of the boiler where the gas envelope surrounding the tube is within approximately 200 deg F of the softening point of the ash. The other critical zone is at temperatures near or below the dew point of the flue gases, where corrosion of the metal also takes place and further aggravates the fouling problem.

The characteristic of the ash content in high-sulphur fuel oil produces a fouling problem which is quite different from that usually experienced with coal, owing to the fact that the fusion point of the ash is in the neighborhood of 1600 F. As may be seen from the schematic cross section of the heating surfaces of the boiler shown in Fig. 11, this temperature zone lies in the first bank of superheater tubes. With coals, the fusion point of the ash is frequently well above 2200 F, which fixes the fouling zone in the boiler-generating tubes. In such instances, it is possible to control to a very large extent the whole problem of fouling by going to a low-heat-release furnace, so that the temperature of the gases leaving the furnace are for the most part below the softening point of the ash. The boiler and superheater tubes for coal-firing are widely spaced in order to provide low velocities for the gases of combustion, which appears to be helpful in preventing the fly ash from depositing on the tubes, and also because the mechanical strength of coal slags is usually greater than that from petroleum-base fuels, thereby increasing the tendency to bridge across between tubes.

In connection with the firing of high-sulphur fuel oil and petroleum coke, interesting proof of the sharply defined temperature conditions which control deposits on boiler heating surfaces was obtained by fanning out the first bank of superheater tubes so that the spacing at the bottom was increased from $3\frac{1}{2}$ to $4\frac{1}{2}$ in. centers for $2\frac{1}{2}$ -in.-OD tubes. This was accomplished simply by inserting 2-in. spacers between the lower ends of the tubes, thus increasing the clear space between tubes from 1 to 2 in. Actually, with only 1 in. of clear space, some of the tubes were much closer than this, or even touching one another due to warpage. The

FIG. 10 METHOD OF FANNING-OUT BOILER SUPERHEATER TUBES TO INCREASE CLEAR SPACE BETWEEN TUBES—OLEUM STEAM PLANT

FIG. 11 TEMPERATURE GRADIENT OF FLUE GASES BEFORE AND AFTER FANNING OUT SUPERHEATER TUBES, AS SHOWN IN FIG. 10

method of accomplishing this is illustrated in Fig. 10, and the effect on the temperature gradient of the flue gases is shown in Fig. 11.

Before making the change just mentioned, in the superheater-tube spacing, the fouling zone was concentrated initially in the first bank of the superheater, and as the deposits continued to build up, the temperatures ultimately were raised in the second bank to the point where fouling would commence in that zone. The tubes were so closely spaced that effective soot-blowing was

impossible. However, after fanning them out, the amount of fouling in the first bank and the first three rows of the second bank was materially reduced, and it was possible to keep these tubes clean by means of soot-blowing. There was some increase in the amount of deposits in the last few rows of the second bank. It has been concluded that this is due to lack of penetration of the soot blowers. It is anticipated that installation of additional blowers between the second and third superheater banks will remove these deposits.

Increasing the spacing by the method described was considered as an experiment in order to determine the optimum spacing of the superheater tubes. However, such a noticeable improvement in the operating periods between cleanings was obtained at nominal expense that nine of the twelve boilers in the three plants are in the process of being changed in a similar manner. The other three boilers, which are designed for coke-firing as well as fuel oil, are to undergo a more radical change in superheater-tube spacing as a further experiment. The conclusion to be drawn from the foregoing experiment appears to be that soot-blowing can be made effective for these special fuels if the optimum spacing of the superheater tubes is predicted correctly. From this optimum point, the indications are that the effectiveness of the blowers will decrease either for narrower or wider spacing.

Additional problems were encountered in the furnace owing to the particular kind of ash found to be present in either the high-sulphur fuel oil or coke derived from the same crude stock. From the analysis of the ash given in Table 4, it can be seen that appreciable quantities of vanadium and nickel are present, and that the

TABLE 4 ANALYSIS OF ASH IN PETROLEUM COKE

Substance	Per cent by weight

(10) Na_2O (calculated)	23.4
Total of items 7-8-9-10	84.7

total of NiO , SO_2 , V_2O_5 , and Na_2O represents nearly 85 per cent of the entire sample. The presence of these compounds introduced a phenomenon of furnace-wall growth which eventually progressed to a point where the expansion spaces at the corners of the furnace walls were completely taken up, thereby setting up very heavy stresses which in turn resulted in serious distortion of the steel members between the buck stays and the furnace walls. This condition was first observed after a period during which approximately 25,000 tons of petroleum coke had been burned.

The furnace walls consist of waterwall tubes which are studded and faced with plastic chrome ore. In the process of combustion, sulphates and vanadates of the alkalis are formed; and these appear to have a strong affinity for the chrome ore and penetrate the pores and cracks which occur during successive cooling and heating of the furnace. Under such temperature reversals these compounds pass back and forth from the solid to the liquid state, thereby penetrating the chrome ore with resultant growth in volume. The coefficient of expansion of the slag is greater than that of the chrome ore, and the combination produces a very dense mass which brings about a progressive growth of the entire wall. The resultant mechanical forces which are set up are sufficient to force the water-wall tubes to spread further apart until all the expansion space in the corners of the furnace walls has been taken up. This condition has been overcome by the addition of more tie bars for holding the waterwall tubes in place, and the substitution of a different type of refractory facing for the tubes.

In Table 5 is shown a rough correlation between the proportion

TABLE 5 PROPORTION OF CRITICAL FUELS BURNED, COMPARED WITH AVERAGE NUMBER OF BOILER SHUTDOWNS PER YEAR FOR EXTERNAL CLEANING OF HEATING SURFACES

Year	Station	Proportion of critical fuels burned, per cent of total	Average number of cleaning outages per year per boiler
1948	Avon	45	2.7
	Martinez	69	2.7
	Oleum	59	1.7
1947	Avon	66	4.0
	Martinez	73	3.0
	Oleum	78	1.7
1946	Avon	92	3.0
	Martinez	70	2.7
	Oleum	73	2.0
1945	Avon	18	1.7
	Martinez	17	1.7
	Oleum	14	1.2

NOTE: The number of cleaning outages in the last column includes the regular annual overhaul and inspection.

of critical fuels burned and the average number of boiler shut-downs per year for external washing of the heating surfaces. It can be noted that, during 1945, on account of the war, much smaller percentages of critical fuels were burned, and the average number of cleaning outages was the lowest during the 4 years shown in the tabulation. However, due to the improvements which are being made in overcoming the problem of deposits, boiler availabilities increased during 1948.

This problem of burning special types of fuels has been treated at some length because it has to do with one of the major points of difference between a conventional plant and the semi-industrial type which is the subject of this paper. On the other hand, the data which have been presented clearly show that, although the problem should not be underestimated in entering upon a joint undertaking of this nature, waste fuels can be burned with reasonable boiler availability, and that operating experience has brought to light the possibility of boiler-design modifications and improved soot-blowing techniques, which should bring these availabilities still closer to what can be obtained with commercial grades of fuel.

RAW-WATER SUPPLY

The large quantities of raw water required for the process evaporators are supplied from a slough in the San Joaquin River about 10 miles north of the Avon steam plant. However, due to a combination of tidal conditions and seasonal variations in river flow, the salt water from San Francisco Bay tends to back up in the river and the salinity of the water becomes prohibitive at certain seasons of the year. Shortly after the Avon station was started up, an alternate supply became available from the Contra Costa Canal which is an irrigation project of the United States Bureau of Reclamation. The source of this canal is located at a higher point up the San Joaquin River, but conditions are such that, at certain seasons of the year, the salinity from Mallard Slough is less than that which prevails in the Contra Costa Canal, and it has been found desirable to switch from one source to the other during the year, as indicated in Fig. 12. The chemical conditioning of this raw water for evaporation involves a formidable treating plant which is illustrated in Fig. 13. The average analyses of the raw water are given for both Mallard Slough and the Contra Costa Canal and the analyses at various points in the treating cycle are also given.

The problem of preparing the raw water for evaporation without carry-over and consequent contamination of the entire system is of major importance. However, it is felt that this is a subject which does not stand out as peculiar to this type of plant, except with respect to the very large quantities of water to be handled. Therefore the matter will not be elaborated here in such detail as has been the case with the special problems directly related to this type of station.

FIG. 12 HISTORICAL RECORD OF SALINITY OF RAW-WATER SOURCES FOR AVON AND MARTINEZ STEAM PLANTS
Vertical arrows indicate time of change-over from one source of supply to the other.)

CONCLUSION

An attempt has been made to point out and evaluate the special problems which enter into the design and operation of a plant of this type. The advantages that are inherent in such a joint undertaking should be obvious, but it is possible to wipe out a large proportion of these benefits by the failure to give proper weight to the various factors involved. It is therefore hoped that the somewhat detailed analysis of the more important problems which have been set forth in this paper will be helpful in developing a sound basis for making a realistic appraisal of any such similar undertaking which might come up for consideration in the future.

Discussion

F. S. CUMMINGS.³ This paper is of particular interest on two points:

1 It gives operating results of a modern high-pressure public-utility generating plant, operating in conjunction with a large industrial plant, requiring both electric energy and large quantities of moderately high-pressure steam for process work.

2 It covers what is believed to be the first published information on the problems of burning, under modern high-pressure boilers, practically all of the waste products from a modern oil refinery.

In the last 25 or 30 years there have been many industrial plants built to supply process steam and electric energy for plant uses. Sometimes these plants operate as independent units, and sometimes they operate in parallel with a public-utility system to better take care of any unbalance in electric and steam requirements of the industry. However, there have been relatively few public-utility plants built for the express purpose not only of supplying electric energy to the utility distribution system, but

³ Vice-President and Chief Engineer, C. C. Moore & Company, Engineers, San Francisco, Calif. Mem. ASME.

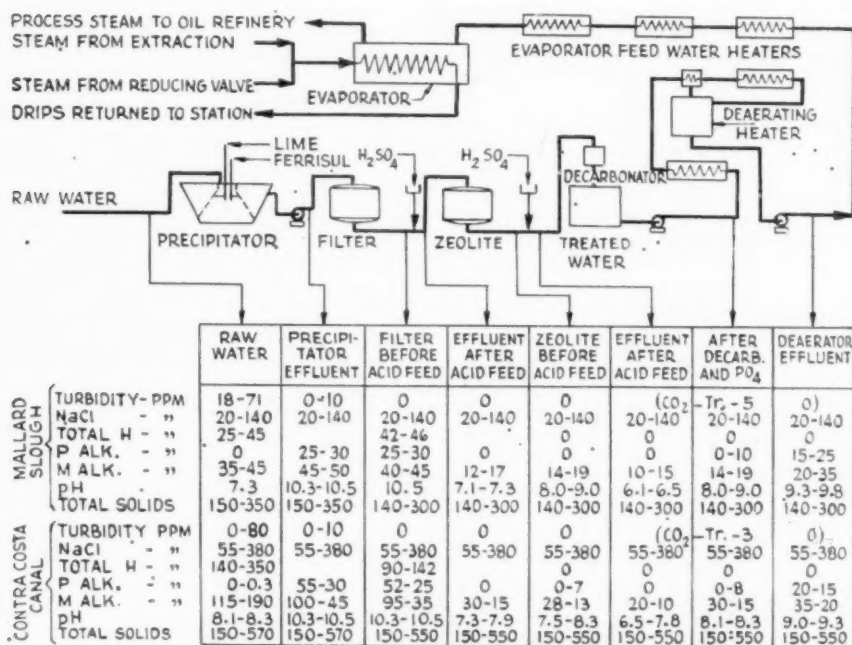

FIG. 13 FLOW CYCLE AND CHEMICAL-TREATING CYCLE FOR RAW-WATER SUPPLY TO PROCESS EVAPORATORS AT AVON AND MARTINEZ STEAM PLANTS

also to supply electric energy and steam for an adjoining industrial plant. Further, there have been still fewer such plants built to operate at high pressures and temperatures.

As pointed out in the paper, both the utility and the industry can gain much by such a tie. The advantages to be gained are so many that future planners should consider them seriously. Probably one of the more important reasons for a utility being reluctant to tie in with an industrial plant has been the fear on the part of the utility that it would lose some of its flexibility in the generation of electric power which of course is its basic reason for existence. The plants discussed in the paper have been in operation for a number of years, and the operation has given ample proof that there need be no serious difficulties.

Until perhaps the last 15 or 20 years, fuel oil was considered to be perhaps the most ideal of fuels. Compared to the use of coal and other fuels, boiler outage was relatively low, maintenance was also relatively low, the elimination of expensive storage,

handling, and burning equipment meant lower first cost, and operation was generally more flexible. All of this has changed in more recent years. The change in quality of fuel oil available during the war years, and changes in refining methods, have created many new problems for the boiler designer and operator—problems which are not always solved by referring to experience in burning coal. Years ago oil-fired boilers were relatively small, of comparatively low pressure, and ran at moderate ratings. Central-station boilers today are of large capacity, high pressure and temperature, and operate at high ratings. These factors have increased the problems confronting the designer and operator.

On the West Coast the quality of fuel oil also has deteriorated because of the decreasing supply of crude, which has necessitated an increased use of crudes which are relatively high in impurities. These impurities are sulphur and sometimes small quantities of rare metal oxides which have a peculiar action on the ash which is in the fuel. While fuel oils themselves many times have these

troublesome characteristics, the various types of waste fuels, burned in the three plants under discussion, produce aggravated difficulties because of the higher percentage of impurities.

It is most interesting to note that boiler and plant design has been such that even the worst of the waste fuels have been handled with some considerable success. The operating experience gained has been most valuable in the design and operation of new units; it is by studying the operating difficulties encountered that future plants can be built with increased reliability equal to the best of modern coal-burning plants.

F. X. GILG.⁴ It may be of interest to show a cross section through the steam-generating units which were installed as part of the Oleum, Avon, and Martinez projects, described by the author.

Fig. 14 herewith shows a cross section through the boilers which are radiant-type single-pass gas flow, designed to generate 200,000 lb. of steam per hr. continuously at 1450 psi and 950 F at the outlet of the superheater. Final steam temperature is controlled by means of a gas by-pass around the superheater at one side of the boiler, the quantity of gas

FIG. 14 CROSS SECTION THROUGH STEAM-GENERATING UNIT AS INSTALLED AT OLEUM, AVON, AND MARTINEZ STATIONS

⁴ Application Engineer, The Babcock & Wilcox Company, New York, N. Y. Mem. ASME.

by-passed being controlled by dampers located in the cooler zone under the economizer.

The furnaces are completely water-cooled and designed to accommodate oil, gas, or pulverized fuel.

The economizer is of the continuous-tube type and extends across the full width of the setting including the superheater by-pass area.

A cold-air by-pass is provided in the tubular air heater so that the tube-metal temperature can be raised to minimize corrosion when burning high-sulphur fuels.

The boilers are installed outdoors with just a protecting roof over them.

As pointed out by the author, experience gained on these units burning refinery-waste fuels has been helpful in designing later units so that the superheater surfaces do not foul up as quickly and can be cleaned by soot blowers in service. As can be seen from the temperatures in Fig. 11 of the paper, it is more complicated than simply providing more space between superheater tubes, because the absorption decreases with wider spacing, resulting in higher gas-temperature levels in the subsequent banks of superheater tubes and the possibility of transferring the troublesome area. It is to be noted that after fanning the lower ends of the first-bank superheater tubes so that the clear space was 2 in. instead of 1 in. between tubes, the temperature of the gases entering the second bank of superheater tubes increased from 1450 F to 1580 F. However, indications are that the wider spacing resulted in less plugging of the first bank of superheater tubes, which was so troublesome from the beginning.

F. G. PHILO.⁵ Experience obtained in burning natural gas and high-impurity fuel oils in large quantities at the Long Beach Steam Station, through evolution, has led to a number of boiler-design, operating, and maintenance betterments which are incorporated in the boiler installation of the Redondo Steam Station which was placed in service late in February, 1948. In connection with the present paper it may be helpful to mention several of these improvements. The more important changes are as follows:

- 1 Elimination of all gas baffles.
- 2 Graded spacing of furnace screen, superheater and economizer tubes.
- 3 Watertight acid-resistant sloping floor and hopper beneath superheaters, economizers, and air preheaters to facilitate water washing.
- 4 Downflow of gases through economizer and air preheater.
- 5 Permanent provision to collect and conduct wash water with dissolved and other solids to a point of convenient disposal.

In a general way, with high-impurity fuel oils, including rather high sulphur content, such as Pacific Coast 400 or Bunker C, the boiler, superheater, economizer, and air-preheater surfaces operate within a very wide range and number of gradations of skin temperatures (on the surfaces of deposits especially) and function quite effectively as fractionating condensers.

Most of the impurities enter the boiler passages in the vapor or gas phase and tend to deposit throughout the heat-transfer system wherever temperature and moisture conditions are favorable for deposit. The situation to a large degree may be likened to the changing nature of deposits often found in successive stages of a steam turbine due to carry-over of solids from the boiler.

Referring to the accompanying sectional outline of one of the Redondo boilers, Fig. 15, the changes previously itemized will be noted as follows:

1 Elimination of all gas baffles facilitates water washing; certain areas may be washed both from front and back.

2 The lateral and "front to back" tube spacings are as given in Table 6 herewith.

Gradation of cross spacing between tubes has prevented appreciable increase of draft loss due to fouling.

Although, at the time of installation, the boilers were equipped with the latest design of retractable mass-action soot blowers, deposits do adhere to the various heating surfaces and cause a gradual but slow reduction in the range of superheater control.

The greatest deposits occur on the surfaces of the economizer tubes. This particular deposit is rather loose and soft and, fortunately, is highly soluble and easily removed with a generous stream of water slushed over the top row of tubes in each of the two tube banks of the economizer. This is done with a very low fire and can be completed in a period of about 2 hr "off-line" at full boiler pressure.

3-4-5-Watertight, acid-resisting floors and soot hoppers, downflow of the gases and wash water in the economizers and air preheaters, and washing toward the cold end of the economizers and the air preheaters, especially in the case of the air preheater, combine to wash deposits out of the preheater instead of through the air preheater.

To those unacquainted with the problem of deposits from relatively high-ash and sulphur fuel oils, it may be of interest to know of the quite effective cleaning job that may be accomplished by the occasional use of natural gas for several days, as a cleaning agent for surfaces fouled by noncombustible residues from fuel oil. Where limited amounts of natural gas are available in oil-burning plants, it has been found good practice to rotate or alternate the firing of gas and oil. The reasons for the cleaning effect of gas are still undetermined.

Operation with regenerative air preheaters to date has been encouraging as most of the troubles previously experienced with the older tubular air-preheater deposits have not been encountered. It is felt that a great deal of the corrosion and deposits difficulties previously experienced with the tubular air preheaters was chargeable to uneven distribution of air and gas flow around and through the individual tubes. Scott Jensen⁶ has surveyed the pattern of gas temperatures from the individual tubes of large preheaters at the Long Beach Steam Station which were installed in 1928-1930. Corrections of local flow rates in the preheaters have raised the lower local gas temperatures sufficiently to mitigate corrosion greatly and also plugging by deposits on the cold ends of the air preheater tubes.

The writer feels that the problem of oil-ash residues has not received its warranted study by the boiler and soot-blower manufacturers. Intensive study of this important problem is suggested as it is reasonable to expect increasing troubles with higher concentrations of oil-impurity residues anticipated from fuel oils produced by improved refinery processes of the future.

W. F. RYAN.⁷ The advantages of co-operation between process

FIG. 15 CROSS SECTION THROUGH STEAM GENERATOR AT REDONDO STATION OF THE SOUTHERN CALIFORNIA EDISON COMPANY
(Maximum capacity 400,000 lb of steam per hr; design pressure 1000 psi; total steam temperature 900 F.)

industries and public utilities for wholesale generation of electric power have never been better stated than by the author in this paper. If these advantages were more widely comprehended, an appreciable portion of steam-generated power in this country might be derived from plants like those described in the paper, with benefit to the national economy from availability of lower-cost electric power, lower-cost process steam, and conservation of our fuel resources. As the author points out, the advantages of the setup should be equitably divided between the utility and the manufacturer. An equitable arrangement is not always easy to arrive at, and it is even less easy to convince both parties that the arrangement is equally advantageous to each. Nevertheless, meticulous and patient appraisal of each detail will be well-rewarded whenever the basic conditions are favorable for such an enterprise.

When these plants were built, the pressures and temperatures selected were probably regarded as the maxima commercially practicable. There should be no obstacle, in the design of future plants, to the use of higher pressures and temperatures. Certainly, if higher pressures and temperatures can be justified for the straight-condensing units in the normal utility plant, there is much greater justification in plants such as these when a substantial portion of the output is generated with a back pressure in excess of 200 psi. Raising the pressure from 1500 to 2500 psi, and the temperature from 940 F to 1050 F increases the energy potential about 8.5 per cent, with 1.5 in. Hg back pressure, but the corresponding increase, with a back pressure of 240 psi, is over 31 per cent. The yield of "by-product" power is correspondingly increased.

Further increase in the yield of by-product power could be effected by interposing a desuperheating heater in the extracted-steam connection between the turbine and the evaporators. The author does not indicate the temperature of the extracted steam, but with a throttle temperature of 940 F, the amount of superheat at 200–240 psi must be substantial. It has been shown by Cross and Wells⁸ that the use of the feedwater to desuperheat this steam before it enters the evaporator provides an increase in the yield of by-product out of all proportion to the cost of the simple equipment required. For the steam conditions at the Pacific Gas & Electric Company plants, the increase would be about 8.0 per cent.

With 2500 psi initial pressure, reheat would be desirable for the condensing part of the cycle. With this reheat taking place at about 470 psi, the combined effect of higher pressure, reheat, and the interposition of a desuperheating heater in the extraction line would increase the yield of by-product power by more than 48 per cent. This larger noncondensing operation probably would justify the use of turbine-generators of 60,000 to 80,000 kw, which might be more suitable for large power systems such as that of P.G. & E.

These thermodynamic considerations are well-known, and relatively unimportant in comparison with the business aspects of this kind of undertaking, and the practical operating results which are so ably reported in this paper. We are greatly indebted to the author and to the Pacific Gas and Electric Company for making these data public. It is hoped that this report may inspire other utilities and other process industries to develop like opportunities to the advantage of themselves, and to the benefit of the public which ultimately profits both from lower costs of power and lower costs of processed products.

H. G. THIELSCHER.⁹ A significant fact is the foresight shown

⁸ "An Improved System in the Application of Noncondensing or Extraction Turbines," by H. W. Cross and E. S. Wells, Jr., Trans. ASME, vol. 62, 1940, pp. 37–40.

⁹ Resident Engineer, Combustion Engineering-Superheater, Inc., New York, N. Y. Mem. ASME.

by the designers of the station described in selecting a steam pressure of 1500 psi and 940 F 12 years ago when that temperature was not at all common, even in central-station practice. This selection of steam conditions leaves the utility in an attractive position today should it ever become necessary to operate these plants as electric-generating stations only.

Fig. 3 of the paper indicates a throttle flow of 680,000 lb per hr for 50,000-kw turbine load and a refinery flow of 275,000 lb of steam per hr. For the steam conditions selected and with a straight regenerative cycle and 4 stages of extraction, we might expect a throttle flow of 450,000 lb for 50,000-kw turbine load. The difference between this figure and the 680,000 lb of steam provided, or 230,000 lb per hr, represents a considerable additional investment in the cost of the boiler plant.

Other major items which make the plant cost more than a conventional electric-generating station are the turbine-generator, process-steam evaporators, process-steam piping, and water-purification plant.

No doubt these factors were taken into consideration when figuring the charge for process steam and electric energy. As an offset to the additional fixed charges imposed by these items, it is to be noted that the heat rate per net kilowatt-hour generated averages much less than that of a conventional plant.

The oil industry generally practices the policy of writing off its investment in new equipment in a few years compared to utility practice of, say, 30 years. It would be interesting to know whether a quick write-off of the extra investment involved in this plant, compared to a conventional generating plant, was figured in arriving at the charges to be made for the products supplied to the refinery.

P. H. WOODS.¹⁰ It has been both a pleasure and a privilege to have participated from its inception in the development of the arrangement for supply of steam and electric power by the Pacific Gas and Electric Company to the oil companies as described in this paper. The author has outlined the principal features of the contract and of the technical problems encountered in the operation of the steam plants. Therefore the writer will limit his comments to the arrangement as seen from the oil-company point of view.

In the 8½ years that have elapsed since utilities were first supplied to us by the Avon Steam Plant, Tide Water Associated Oil Company has had little reason to regret entering into the contract. The oil company is in the business of making petroleum products, and we have been quite happy to leave generation of power in the hands of the utility—that is, the business they are in.

At the time the present arrangement was first suggested, Associated was in the midst of a major plant expansion which included enlargement of our steam-generating facilities. We had, in fact, entered into a contract for construction of a new 850-psi-pressure boiler plant and were seriously considering installation of electric-generating facilities as well. Fortunately, as we see it now, the suggestion came early enough in our program to permit cancellation of our boiler-construction contract and to switch to the present setup.

Before the Avon Steam Plant was built, Associated generated all of its own steam, partly at 150 psi pressure, and partly at 250 psi, and purchased electric energy from the utility through a single substation at 2400 volts. Now we take delivery of steam at 165 psi pressure with some superheat, and receive electric power through three substations. The old 150-psi boilers have been out of service for some years, as the contract maximum on steam gives us a comfortable margin over actual demand. The arrange-

¹⁰ Chief Engineer, Tide Water Associated Oil Company, Associated, Calif. Mem. ASME.

nient has encouraged us to electrify new construction for the sake of economy in operating costs, and in many cases has enabled us to replace old steam-driven units with electric drives at substantial savings.

Economies have accrued in another direction as well. Formerly we burned sludges and other wastes in a disposal furnace. These noncommercial products are now turned over to the utility in part payment for energy. Some conditioning of these fuels is necessary, but generally this can be accomplished by minor modifications in the manufacturing process. Refinery operating personnel works in close co-operation with steam-plant operators as to characteristics of this type of fuel.

Reliability of supply of electric energy to the refinery has been improved materially. Our second and third substations are fed directly from the steam plant 12-ky bus, and interruptions to this supply are rarities. This factor is important to us, as process units built since 1940 are much more complex than older units, therefore more difficult to get back on stream after a power interruption, and shutdown time is expensive.

In normal steam-plant operation, three evaporators are on-stream to supply the refinery steam load. Fouling requires that they be taken down, one at a time, for periodic cleaning. At such times, when availability is down one third, Associated supplies the difference from its 250-psi system. This second refinery steam system is necessary for process reasons and was in existence prior to the time the steam-plant studies were begun. For several reasons, both process wise and economic, no attempt was made to incorporate a 250-psi steam source into the steam-plant design.

AUTHOR'S CLOSURE

The author is very much indebted to all of those who have presented written discussions. It is felt that all of the remarks are timely and constructive, and have added materially to the value of this paper. It is interesting to note the great amount of interest displayed in the subject of external fouling of boiler heating surfaces.

The observation by Mr. Cummings, to the effect that the problems encountered in burning present-day fuel oil are not always solved by referring to experience in burning coal, has been well substantiated by the experiences of plants on the eastern seaboard which have recently changed from coal to fuel-oil firing. Such plants, originally designed for firing with coal, have changed to fuel oil because of the availability of the latter fuel at competitive prices. In some instances the resulting boiler availabilities have been reduced below that which is obtained on the Pacific Coast with the similar types of fuel oil. This is partly due to the fact that, when firing with fuel oil, deposits tend to build up in the first superheater bank which, in a boiler designed for coal firing, sometimes consists of as many as 12 or 14 rows of tubes, thus making it impossible to obtain effective soot-blower penetration. As has already been pointed out, slag deposits do not usually occur in this zone when firing coal due to the usually much higher fusion point of the ash. Effective results from soot blowing cannot be obtained on superheater banks deeper than about six or eight rows of tubes. Satisfactory penetration is obtained by blowing from both the front and back of such banks with mass type blowers.

With reference to the last paragraph of Mr. Gilg's discussion, it is important to emphasize that the one inch clear space between tubes in the first superheater bank cannot consistently be maintained due to a certain amount of warpage which takes place in this temperature zone, thereby producing a very serious obstruction to the path of the gases and making it almost impossible to obtain effective soot-blower penetration. A cross section of one of the boilers is included as Fig. 14 in Mr. Gilg's dis-

cussion, and by comparing this with Section AA or BB in Fig. 10 representing the lateral spacing of the tubes in the first superheater banks, it will be noted that there are three rows of relatively wide-spaced tubes at the front of this bank. This arrangement provides a clear space of 3 in. between these tubes, but tends to reduce the effective penetration of the soot blowers through the more closely spaced tubes because of the interference of these first three rows, which also have the effect of keeping the soot blowers further away from the close-spaced rows. Thus the wide-spaced rows, particularly in view of the fact that they are staggered, appear to do more harm than good from the standpoint of fouling of the heating surfaces.

As an experiment on one boiler, the first two staggered rows of wide-spaced tubes have been moved back into line with the third row, thus having the effect of adding one more close-spaced row in place of the three wide-spaced rows, and making it possible to move the soot blowers a distance of approximately 10 in. closer to the close-spaced rows in that bank. This is very important from the standpoint of effective soot-blower penetration, and there is every indication that this modified tube arrangement, plus 2 in. clear space between the tubes and the proper installation of mass blowers, will make it possible to keep this first superheater bank clean for considerably longer periods of time. It has also been demonstrated that the effectiveness of mass-type blowers can be greatly increased by the addition of specific quantities of water. This applies to either air or steam blowers, and results in far less temperature shock than occurs when 100 per cent water washing is resorted to under load. A few plants have actually adopted the latter practice at intervals of, say, 30 days to augment regular soot blowing.

Mr. Philo's discussion is very pertinent and brings out some of the design modifications which have been adopted almost universally on recent Pacific Coast installations. The provisions cited in Item 3 of Mr. Philo's discussion, to facilitate water washing of the boiler while it is off the line, tend to produce a better job of cleaning with less boiler outage time. In connection with Item 2, it has already been emphasized by the author that increased spacing between superheater tubes to some figure greater than 1 in., particularly in the first bank, is highly desirable. However, it does not follow that, by progressively increasing this spacing, we shall obtain correspondingly improved results from the standpoint of less deposits. Operating experience during the past year suggests that there is an optimum spacing which will obviate abnormal restriction of the gases due to slag deposits and at the same time provide for maximum effectiveness of the soot blowers. It is fairly certain that this optimum clear spacing is somewhere between 2 and 3 in. for the superheater banks, and approximately 2 in. for the economizer section. For oil fuel, it is doubtful whether spacing as little as one inch can be justified at any point in either the superheater or economizer sections.

The investigation conducted by Scott Jensen and referred to by Mr. Philo in connection with the survey of the pattern of gas temperatures leaving individual tubes of large tubular air preheaters, represents a valuable contribution to the problem. It provides a basis for the installation of baffles so that proper gas-flow distribution is obtained throughout the preheater, thereby eliminating localized low-temperature zones which have a major influence on both corrosion and plugging by deposits at the cold end of the preheater.

With reference to Mr. Ryan's comment on the gains which can be realized by desuperheating the extraction steam before it enters the evaporator, it should be stated that this has been accomplished, at least in part, by means of a steam-to-steam heat exchanger whereby the superheat in the high-pressure turbine exhaust is removed by adding superheat to the evaporator vapor. The refineries require 50 F superheat in the process steam at the

point of delivery. In the last paragraph of Mr. Ryan's discussion he has emphasized the importance of the business aspects of this kind of undertaking. This is indeed true because it is absolutely essential to make proper allowance in the financial setup for the various technical factors which enter into the operation of such an undertaking. However, it cannot be too strongly emphasized that an intimate knowledge of the practical operating problems and related technical factors are the essential prerequisites to the conclusion of a satisfactory business arrangement between the two parties.

In connection with Mr. Thielscher's remarks regarding the increased investment in boiler plant over what would be required for a conventional plant, it should be pointed out that additional boiler capacity is required to generate the process steam which is sold to the oil refineries. The working agreement, of course, provides that the revenue from such steam sales will be adequate to

pay for this incremental capacity, and it should also be pointed out that the additional high-pressure steam generates by-product power in the high-pressure turbine at extremely high efficiencies. In reply to Mr. Thielscher's question in the last paragraph of his remarks, it should be stated that all three of the contracts with the oil refineries were written for a period of 20 years with provisions for automatic extension beyond that period unless twelve months' written notice is given by either party stating its desire to terminate the agreement.

It is gratifying that Mr. Woods has contributed to the discussion by giving the point of view of the oil refinery, setting forth the advantages which have accrued to them as a result of this undertaking. We should like to add that the day-to-day working relations between the respective operating personnel of the utility and the refinery have been highly satisfactory and consistently take place in the spirit of fine co-operation.

Steam-Electric Power Expansion in Southern California

By W. L. CHADWICK,¹ LOS ANGELES, CALIF.

This paper presents the background of the postwar expansion of steam power in Southern California, the requirements of the area served, a brief discussion of some of the war and postwar influences bearing upon power needs, the disposition of the new generation, the design trends in the area, and the influences bearing thereon. A description is given of the major features of the Redondo Steam Station of the Southern California Edison Company.

INTRODUCTION

FOLLOWING the late war and the necessity of restricting to the maximum the manufacture and installation of electric power-generating equipment of every kind and also the purposeful loading of all existing reserve generation with war production, it has been a common experience throughout the country to have postwar power loads increase more rapidly than new generation capacity could be provided. Perhaps, however, the situation in California is sufficiently different to be noteworthy and of interest.

A companion paper² treats of the northern part of the state; this paper will treat of the southern part. California may be said to consist economically of three metropolitan and industrial areas, and a large agricultural hinterland in which there are also some industrial and residential centers. The metropolitan areas of course are those around San Francisco Bay in Northern California, and those around Los Angeles and San Diego in Southern California. Although geographically, Southern California includes only ten of the state's 58 counties and only 37 per cent of the area of the state, it contains more than one half of the state's population and utilizes about one half of the electric power. Another fact which has a large bearing on power resources, particularly hydraulic power, is that the Southern California area possesses only about 1 per cent of the state's water resources.

Because fuel was then scarce and steam power generation was inefficient, the first electric power developed in the state was hydraulic. However, during the first decade of power development, a severe drought so reduced the water supply that some systems found it necessary to move boilers and engines to hydro plants to meet the deficiencies in the hydro output. Since that time, steam power has been an intimate part of power supply, but being always more costly to operate than hydro, it has been used only as complementary or supplementary energy. This condition has begun to change, and in the future base-load steam generation will be required in increasing amounts.

SOUTHERN CALIFORNIA POWER SYSTEMS

Southern California is served by eight different power systems.

¹ Manager of Engineering Department, Southern California Edison Company. Mem. ASME.

² "Postwar Planning for Steam Capacity in Northern California," by C. C. Welchel and W. R. Johnson, published in this issue of the Transactions, pp. 237-246.

Contributed by the Power Division and presented at the Semi-Annual Meeting, San Francisco, Calif., June 27-30, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-SA-16.

The city of Los Angeles is supplied by its municipal Department of Water and Power, with energy generated (a) in its own hydro plants, (b) at Hoover Dam, and (c) in three steam stations. The cities of Pasadena, Glendale, and Burbank have municipally owned systems each supplied from its own steam station, in addition to purchasing hydro energy from Hoover Dam. The Imperial Irrigation District supplies energy generated by hydro along the All American Canal and by Diesel to the Imperial Valley area, and is now constructing a steam station. The metropolitan area surrounding San Diego is served by the San Diego Gas & Electric Company through a system which gets most of its energy from base-load steam, but obtains the remainder from wholesale purchases.

A portion of the eastern side of the coastal plain and some of the desert area is served by California Electric Power Company through a system supplied mainly by hydro plants in the Sierra Nevada Mountains, and by purchases from Hoover Dam and other agencies. The remainder of the Southern California area is served by Southern California Edison Company with energy supplied from Sierra Nevada and other hydro plants, from Hoover Dam, and from two large steam stations, a total system capacity of 1,583,000 kw. Further detail on these systems and their generating capacities are given in Table I, and the map, Fig. 1.

POWER RESOURCES

At the end of the war the power resources of Southern California systems consisted of a total of 2,535,000 kw in operating capacity, installed by the eight agencies; 65.5 per cent of this capacity was hydro, 33.2 per cent was steam, and 1.3 per cent Diesel. Of the hydro, 39.6 per cent of the installed capacity was in 30 plants in the Sierra Nevada Mountains, or in plants utilizing water brought from those mountains; 59.4 per cent was at Hoover Dam, and 1 per cent was in miscellaneous smaller plants. Hydro energy output is ordinarily considered on three bases, namely, (1) that for a year of average water supply, (2) that for a year of low water supply, i.e., a dry year, and (3) that for a year of exceptional water supply, i.e., a wet year. These outputs vary from 6,579,000 kwhr for a dry year to 9,036,000 kwhr for an average year to 10,470,000 kwhr for a wet year. In other words, there is about 27 per cent less in a dry year than during an average year, and about 16 per cent more in a wet year than in an average. Except for the effect of the large storage at Hoover Dam, there would be 50 per cent less in a dry than in an average year.

This situation presents the basic need for steam generation up to the time the war began. Ordinarily, sufficient reserves are maintained either in stored water or steam-generating capacity to meet not only emergency system needs, resulting from breakdowns and seasonal and other peaks, but also for the full deficiency which occurs in a dry year. It is usually considered that about 40 per cent of a system's total capacity is required in steam generation to meet these needs.

WAR-END AND MORE RECENT CONDITIONS

During the war the presence of reserve capacity in Southern California led the War Production Board to locate several defense plants, including one each for magnesium and aluminum reduction, in the area. The effect of these additions was to reduce

the reserves to the point where load curtailment would have been necessary in a year of subnormal water supply. As the war ended, it was generally thought that postwar adjustment would reduce considerably the need for industrial power and hence allow a period during which to regain reserves by building new

FIG. 1 GENERAL SCHEME OF POWER SYSTEMS SERVING SOUTHERN CALIFORNIA

capacity. Although industrial load did drop for a time, its effect was more than offset by expanding energy use in other classifications.

By the first of 1946 it was apparent that in California, as well as elsewhere in the country, there would be no respite, but that the load, at least for some time, would increase faster than new generation could be built. From over the nation, orders were placed much faster than turbines, generators, and transformers could be built. Delivery promises increased from 16 months to 39. Strikes of all kinds during 1946 added months to delivery expectations.

Population Trend. In the meantime, population and loads were growing. Population in Southern California increased 47 per cent between 1940 and 1948. On the Southern California Edison Company's system during the 4 years between January, 1944, when voluntary wartime power rationing in this area ceased, and January, 1948, residential power use increased 52 per cent, commercial use increased 58 per cent, agricultural 75 per cent, and industrial 18.6 per cent. The over-all increase was 41 per cent.

Conditions in 1948. Combined with these influences, rainfall in the early part of 1948 was the lowest for many years, not only causing hydro production to fall off all over the state but also greatly increasing the demand for power for off-season irrigation pumping. In some areas, curtailment became necessary. Southern California had been successful enough in building new steam generation so that when that new capacity was combined with daylight saving and good rains, curtailment there was unnecessary. Also, by co-operative pooling of generating resources, it was possible to transmit large blocks of energy to the curtailed areas with the combined fortunate result that curtailment anywhere in the state was short-lived.

SOUTHERN CALIFORNIA CONDITIONS AFFECTING STEAM-POWER EXPANSION

Southern California steam-power expansion has been noteworthy for the following characteristics and developments:

- 1 The rapid increase in the steam-hydro ratio during the past 5 years.
- 2 The use of moderate steam pressures and temperatures.
- 3 Exclusive use of natural gas and oil but with space allowance for future coal.
- 4 The earliest use of outdoor plant construction.
- 5 The use of special operating methods, controls, and construction to obtain minimum-time load pickup from minimum to maximum.
- 6 Extensive use of high-pressure mechanical oil atomization.
- 7 Successful use of thermal control of marine fouling organisms.
- 8 The recent field rebuilding of three large-sized turbine generators during conversion from 50 to 60-cycle operation.

Hydro-Steam Ratio. As noted previously, at the end of the war the capacity serving Southern California was 2,535,000 kw consisting of 1,659,000 kw of hydro, 844,000 kw of steam, and a small amount of Diesel. Percentage-wise for hydro and steam, this amounts to 65.5 and 33.2 per cent, respectively. Since that date (that is, to January 1, 1949) 34,000 kw of hydro and 388,000 kw of steam have been added, bringing the steam capacity currently to 41.7 per cent. Installations now in design and under construction will bring this ratio to 54.4 per cent hydro, 44.8 per cent steam by January, 1952 (Table 2).

Moderate Pressures Used. To the present time, two influences have tended to keep steam-power developments in Southern California in the moderate pressure and temperature range, namely, (1) relatively low cost of fuel because of the area being figuratively on top of large oil and gas fields, (2) availability of large

quantities of relatively cheap hydro power and the resulting low load factor available for steam operation. Under the latter conditions, 35 per cent is a fair estimate of steam-power load factor. Accordingly, economy has required that new installations be designed and built for the pressures around 850 psi and temperatures of 900 F. With the increase in fuel-oil cost from 18 cents per million Btu to 36.1 cents between the war's end and January, 1949, and waning additional projects for hydro development, interest in more economical cycles is keener. One turbine is on order for 1250 psi 950 F, but no plant so far has been built in the area to utilize the reheat cycle.

Gas and Fuel Oil Only. Prior to the war, fuel gas was in abundant supply at costs of from 9 to 11 cents per million Btu, and oil at about 13 cents. With the increase in demand during the war for gas for industrial and domestic heating, except where gas could be obtained by direct purchases from the oil fields for boiler use, it became available only on a "dump" basis. This means that during warm weather when domestic use is light, and on week ends and holidays when industrial use is light, gas for power generation may be had in quantity, but there is no firm supply except where obtained by direct field purchase. Pipe-line importations are now being made from Texas, and others are in prospect, but again they afford no firm supply. As a result, power generation is principally supported by oil fuel. Some petroleum coke has been available but not in sufficient supply to be important.

As previously stated, no Southern California plant so far has been equipped with coal-handling and burning equipment although several have been built with space provision for bunkers, ash hoppers, pulverizers, and burning equipment.

A rough comparison of the cost of the three fuels under present (February, 1949) conditions is gas about 30 cents per million Btu, oil 31.2 cents to 32 cents per million Btu, depending upon the viscosity supplied, coal from Southern Utah about 44.7 cents per million Btu. With a large increase in fuel-oil stocks during recent months, oil prices for firm delivery have broken somewhat, backing off any immediate necessity for considering coal fuel seriously.

Early Use of Outdoor Construction. Mild weather and economy led to outdoor design for the two plants built by the cities of Burbank and Glendale about 10 years ago, two of the first to make use of such construction. The new Redondo Station of Southern California Edison Company has outdoor boilers, air preheaters, fans, and oil heaters. Three stations have been built on the unit principle with one boiler per turbine unit. Further use of this principle in the near future seems certain.

Quick Pickup Important. Because of the position in the load curve which steam power must take with respect to hydro, and hence of the frequent necessity of steam standing by at minimum loads for immediate operation in the event of an emergency, such as transmission-line or equipment loss, close attention is given in Southern California stations to the minimum load pickup time. The Redondo Station of Southern California Edison Company, for instance, is designed to increase from 5 per cent to full load in 15 sec. Other stations on systems depending upon long transmission lines for an important part of their resources have similar features.

High-Pressure Mechanical Atomization. With the increase in the use of cracking and other newer refining techniques, the production of fuel oil has passed from one in which this fuel was crude oil with the lighter and more valuable fractions removed by distillation to one where it is now a refinery residuum carrying tars, free carbon, and other heavy ends, plus considerable amounts of combustible and noncombustible residual chemicals. The resulting product while containing around 6,250,000 Btu per bbl possesses viscosities as high as 190 sec SSF and averages around 175

see SSF for Bunker C fuel. This heavier fuel requires heating to between 80 F and 100 F to permit its conveyance from tanks to final heaters where temperature is increased to 200-210 F before supply to the burners. Further, this fuel produces deposits which adhere to closely spaced heat-transfer surfaces, particularly in superheaters, economizer and preheater sections which require washing down of external surfaces to permit maintaining anywhere near normal heat absorption.

Further, with the increased industrial use of fuel oil in the area, the need to minimize smoke emission, because of the special topographical and meteorological characteristics of the Southern California coastal area, has also made efficient combustion of first-order importance. To meet this need, a burner and supply system has been developed which utilizes a maximum burner supply pressure of 900 psi, obtained by screw pumps in the primary fuel-supply lines and booster pump connected to a recirculation line, which permits maintaining a burner pressure of not less than 300 psi at minimum load. The result is (1) wider range (1 to 20) between minimum and maximum boiler load, and (2) finer atomization, and hence better and more smoke-free combustion.

REDONDO STATION

Replaces Former Station. The Redondo Steam Station of the Southern California Edison Company is situated directly on the Pacific Ocean at Redondo Beach on an enlargement of the site of an earlier station which was considered uniquely efficient in its day. That original station was built a little more than 40 years ago and contained three 5000-kw General Electric generators, each driven at 100 rpm between two double angle-compound McIntosh & Seymour reciprocating engines supplied with steam at 175 psi and 475 F. The design and construction contract provided for a bonus payment for efficiency better than 170 kw-hr per bbl of fuel oil (about 36,760 Btu per kw-hr). Performance was 50 per cent above this requirement, earning a handsome bonus for its builders. Strangely enough, the advance in steam power generation was so rapid that within less than 4 years a turbine-driven generator was added, making the original units obsolete. Seventeen years later the station was sufficiently obsolete to put it only on the very peak of the load curve, and in another 9 years it was decommissioned and its boilers salvaged. The building was wrecked to permit construction of the new Redondo Steam Station.

Necessary to Utilize Previously Designed Equipment. Design of the new station was started early in 1946, at a time when (1) there was an unprecedented shortage of designers and draftsmen not only for station design but for equipment design and development, (2) strikes were tying up the entire production of the major electrical-equipment manufacturers and such basic industries as steel, coal, and transportation. Postwar adjustments were further delaying deliveries of power-plant equipment of all kinds.

In spite of these influences, it was necessary to have the new station in operation at the earliest practicable date. To offset these delays as much as possible, all major equipment was specified so that proposals could be offered for equipment which had been previously designed and preferably used, thus minimizing design and manufacturing time.

The joint AIEE-ASME Standards Committee had only recently issued its preferred standards for turbine generators, and some design work had been done on the largest or 60/66,000-kw size. Use of these standards and the estimated probable load factor for the station on the combined hydro system, fixed steam conditions at 850 psi and 900 F and turbine speed at 3600 rpm. One each General Electric and Westinghouse units were purchased at the outset, and one each additional late in 1946.

Boilers also were specified to fit radiant types which previously

had been built and used successfully. Multiple and single boilers per unit were considered, but, although more expensive, multiple boilers were selected because, under system conditions, they afforded the greatest reliability and flexibility. To serve the first two units, four 400,000 lb per hr Babcock & Wilcox boilers were provided affording one spare. The final installation will include seven such boilers for four turbines, also affording one spare.

Station Arrangement. The station is laid out with the turbine generators arranged longitudinally along the center of a turbine building 73 ft wide and 485 ft long. A 45-ft-wide auxiliary and control bay parallels this room and forms the firing aisle for the seven boilers. One 200-ft reinforced-concrete stack is provided for each pair of boilers. The boilers, preheaters, forced- and induced-draft fans, secondary fuel-oil heaters, and deaerating heaters are outdoors on the inshore side of the turbine building. Because of the salt-spray-laden fogs which occur along the California coast, no consideration was given to outdoor turbine settings.

Cooling-Water System Design. The coast along which the Redondo Station is situated is exposed and subjected to heavy waves during the late fall, winter, and early spring. The original station had used an exposed vacuum-primed syphon pipe line with 9-ft drop legs set in the surf line to supply circulating water. This system was frequently in trouble from sand, seaweed accumulations, and storm damage. In designing the new station, every effort was made to afford a trouble-free circulating-water system. To obtain this objective, it was considered necessary (1) to keep the pipe lines below the ocean floor; (2) to keep the lines under positive pressure; (3) to avoid any exposed structure; (4) to extend the lines far enough seaward to set the intakes in water deep enough to afford 20 ft of water below low tide, and in order to avoid sand entrapment, to set the intake chime or inflow lip not less than 10 ft above the ocean floor; (5) to afford means of controlling marine fouling organisms which would make shutdown of the pipe lines for cleaning unnecessary. To effectuate the first conditions, both the intake and discharge lines are built of 10-ft-diam precast lock-joint concrete-pipe sections 16 ft in length laid below the ocean floor. The intakes are vertical tee sections 14 ft diam at the end of the 10-ft lines and set in 32 ft of water.

Marine Fouling Control. To control fouling organisms, an extensive investigation of chlorine injection was carried out, but previously it had been observed at the company's Long Beach Station that although the intake tunnels accumulated 4 to 6 in. of marine growth during the growing season, almost no growth occurred in the discharge tunnels. The only reason assignable for the difference was the difference in circulating-water temperatures. Using this long-time laboratory observation, it was decided to provide for fouling control both by means of chlorination and by periodically raising the temperature of the lines by alternately using each as a discharge. To check the possibility of satisfactory control by such means, the assistance of marine biochemists was sought, particularly that of Dr. D. L. Fox, of Scripps Institute of Oceanography.

The eventual solution was two separate 10-ft-diam lines extending an average of 1900 ft offshore where each is provided with an intake structure. These structures were set 200 ft apart, diagonal to the beach, to minimize recirculation. To permit alternate use as discharge and intake and likewise to enable chlorination without the need for chlorination lines extending seaward, a reversing chamber was provided on shore where flows may be reversed in 5 min and recirculated to build up any desired discharge temperature. By chlorinating the discharge line only and reversing pipe lines within the lethal chlorination cycle, all chlorine injection could be accomplished on shore.

Originally, it was considered that it might be necessary both to chlorinate and to elevate temperature and to put each line through such a cycle as frequently as each 8 hr. So far, control by heat alone has been so satisfactory that no chlorine has yet been used in the offshore lines. Furthermore, reversals only once each 2 weeks with temperature elevation to 95 F for 6 to 7 hr, to 102 F for 1½ hr have killed off all organisms before they could mature to objectionable size. The arrangement of these features is shown diagrammatically in Fig. 2.

FIG. 2 SCHEMATIC DIAGRAM OF COOLING-WATER SYSTEMS AND PROVISIONS FOR REVERSING FLOW, REDONDO STEAM STATION

Cooling-Water Lines a Difficult Construction Problem. Construction of the cooling-water lines proved the most difficult part of the project but was successfully accomplished by Maceo Corporation, the contractors, without delaying the operation of the station. Pipe laying was done entirely under water by divers served from a temporary trestle supporting excavating equipment, and a gantry crane for pipe handling. The courage and skill shown in handling the 42-ton sections suspended by slings and cable hoists in depths up to 50 ft, while subjected to fairly high seas, is a fine tribute to the construction fraternity, particularly since the visibility of a diver was often less than 1 ft, making work by touch only necessary most of the time.

Cooling-Water and Condensate System. Flow into and out of the reversing chamber is controlled by motor-operated welded steel gates, 7 ft × 10 ft. Automatic controls pair the gates during the reversing process. Trash racks with traveling rakes and stainless-steel revolving screens prevent the passage of fish or mats of seaweed into the pump chamber. Pumping to each condenser is by means of two vertical 25,000-gpm centrifugal pumps driven by two-speed motors for ease of adjustment from stand-by service to full load. Circulating-water temperatures vary from 55 to 70 F. The condensers are of Ingersoll-Rand manufacture and have 42,500 sq ft of surface. Water boxes and hot wells are divided. Condensate and condensate booster pumps are provided in duplicate with each able to return the condensate from 70,000 kw of load with all heaters in service. Three boiler feed pumps of 785 gpm capacity at 1100 psi are provided for each unit with a steam-driven pump for emergency use on either of each pair of units.

Boilers. All boilers are interconnected on the steam, the feed-water, and fuel sides. Each boiler is equipped with an outside heat-exchanger type of attenuator. Each also is provided with an extra large main steam drum (72 in.) to protect against carry-over during water swell on quick load pickup. Each boiler is provided with automatic equipment which performs the following functions:

- Controls the flow of fuel to the burners.
- Controls the induced-draft-fan inlet louvers and outlet damper, except as modified by the fuel-air ratio controller to maintain a preset metered-fuel-air ratio.
- Controls the forced-draft-fan inlet vanes and outlet damper, except as modified by the furnace-draft controller to maintain a preset furnace draft.

Combustion Control. The combustion-control system was designed specifically for quick load pickup and also for wide load range. The following features were incorporated into the design:

- 1 Steam flow rather than steam pressure provides the impulse to increase the supply of fuel and air.
- 2 Air loading pressure is transmitted direct and simultaneously to the controls for fuel, air volume, and draft.
- 3 Control drives are of the "high-speed" type with extra large pilot valves and air-supply lines for rapid admission of operating air.
- 4 Combustion air is measured by a Venturi section in the air duct rather than being measured subsequent to combustion, thereby decreasing the lag in adjusting air flow to correspond to steam flow.

Fuel System. After primary heating, fuel oil is forced at about 725 psig by Sier-Bath screw pumps, to the main oil heaters adjacent to the boilers where it is raised to about 200 F, and forced to the "constant differential" pumps which raise the pressure to the burners to a full-load pressure of 900 psig and 200 F. The constant differential pumps afford a 20 to 1 load range. Automatic controls are provided in this system to start additional fuel-oil pumps in accordance with load demands, to control recirculation of oil to storage tanks, and to control flow of steam used for heating the oil. Furnace and burner protection is obtained through interlocking controls which shut off fuel to the burners if:

- (a) Oil-supply pressure is low.
- (b) Fan motors fail.
- (c) Furnace has not been purged prior to "lighting off."

Turbine Generators. As previously stated, the turbine generators are the largest AIEE-ASME Preferred Standard, namely, 60,000/66,000 kw tandem-compound 850 psi, 900 F, 3600 rpm units, 13.8 kv voltage, 0.85 short-circuit ratio, built for either 0.5 or 15 psi hydrogen pressure. The heat balance for these units and the station is shown in Fig. 3. Each of the first two units has been tested and operated at loads to prove a safe output of 66,000 kw net.

Auxiliary Power. Two 6000-kw, 15-sec response, noncondensing house sets provide auxiliary power in the event a system voltage or frequency drop threatens the auxiliary power supply ordinarily supplied by two transformer banks connected to the system. On a drop in system voltage, these sets start automatically from standstill and come to full speed and voltage ready to carry full auxiliary load in 15 sec, but must be connected manually to the load at the time the auxiliary banks are disconnected from the system.

GENERAL

Each generator is connected to a 70,000-kva transformer bank. The output of the plant is controlled by a double bus switchyard and is transmitted over six 69-kv transmission lines to a major transmission substation about 5 miles away.

The station structures include an administration and service wing where all offices, shops, and chemical laboratory are housed. Because the region is subject to earthquakes, all structures are designed for a seismic coefficient of 0.2 gravity. This factor is twice that required for public school buildings in the state but is selected in the public interest to assure service continuity should a serious earthquake affect the area.

The station is equipped to burn either gas or fuel oil and space has been provided for pulverized-coal equipment should such become necessary. Some gas is available direct from the fields, but the principal fuel is oil. Storage is provided on the site for 220,000 bbl.

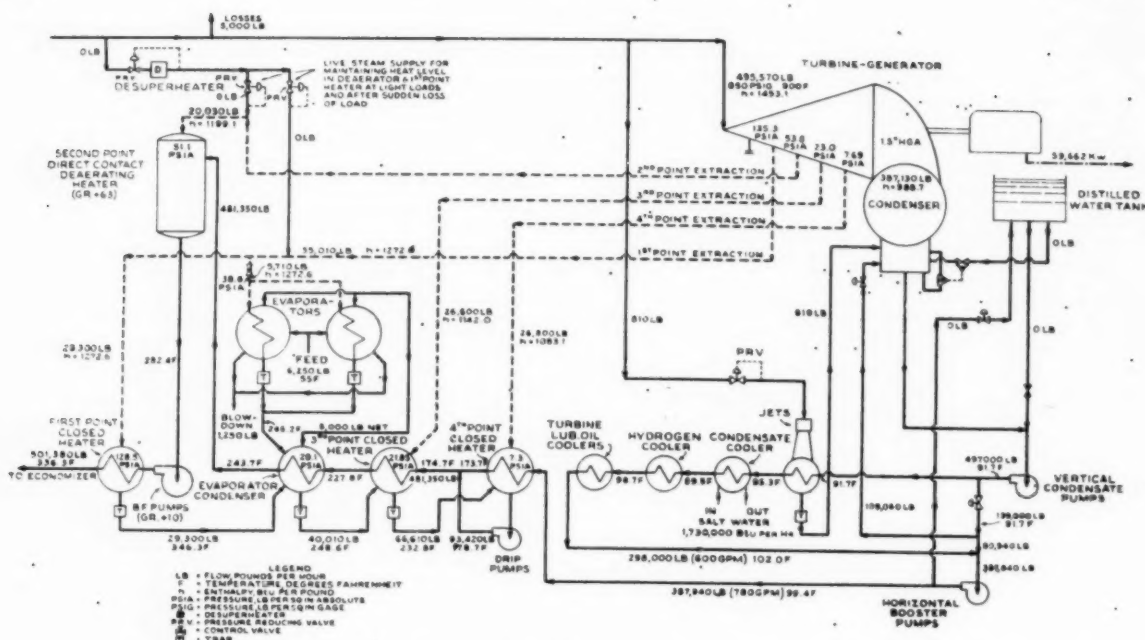

FIG. 3 HEAT-BALANCE DIAGRAM, REDONDO STEAM STATION OF THE SOUTHERN CALIFORNIA EDISON COMPANY

Because of the demand in California during late 1947, and early 1948, for every possible kilowatt of generating capacity, construction of the Redondo Station was under heavy pressure. The first turbine generator was erected from receipt of bedplate to first synchronization with the system in 70 elapsed days, and the second in 51 days. So urgent was the need for the station that it was put into operation as soon as the fundamentally essential manual controls could be completed, and several months ahead of the time when it would have been possible to provide a fully tested and automatically controlled plant. In spite of many threatened construction delays because of postponed equipment deliveries, the station was delivering energy to the system less than 18 months after excavation on the site was started. Operators, engineers, and construction men all co-operated to the latter end. Base-load operation has been the order of the day ever since the first unit was first put on the line.

The station was designed and constructed by the Stone and Webster Engineering Corporation in close collaboration with the Engineering and Operating Departments of the Southern California Edison Company.

FIELD REBUILDING OF LARGE UNITS FOR FREQUENCY CONVERSION

Incidental to conversion of most of the Southern California Edison Company power system for operation at 60 cycles instead of 50 cycles, it was necessary to rebuild two 100,000-kw 450-psi 750 F tandem-compound double-flow General Electric and one 60,000-kw 400-psi 700 F single-cylinder General Electric turbine generators in the field. In each instance it was necessary to replace the high-pressure casings, high and low-pressure spindle, front bearing pedestal, the governor, and the generator field. Further, to allow for the higher speed and greater steam space, it was necessary to reduce the stages in the larger machines from 21 to 17, and in the smaller machine from 20 to 17. This latter required machining new ledges for the new diaphragms.

All parts were manufactured in the factory and shipped to the field without benefit of check assembly of low-pressure parts.

The machining of the intermediate and low-pressure casings was accomplished by field forces of the manufacturer, using a large boring bar operating in the bearings of the turbine. The first job was on one of the 100,000-kw machines and was completed during a 4½ months' outage, the second was completed in 4 months, and the third in 3½ months. Each machine went into service immediately after it was dried out and without clearance, balance, or other adjustment being necessary. All three were delicate and difficult shop and field manufacturing jobs most competently completed.

In the process of rebuilding, 10,000 kw additional capacity was built into each of the larger machines and nearly as much into the smaller one.

With an expansion of 760,000 kw in steam-generating capacity either constructed or in progress since the end of the war, the power systems of Southern California are determined that power supply to that area shall be in time and enough.

Discussion

F. X. GILG.² The steam-generating equipment for Redondo as furnished by the writer's company consisted of four radiant boilers which were placed in service during the early part of 1948, and three additional radiant boilers of identical design which are about ready to be placed in operation. We would like to describe the principal features of the steam-generating equipment.

Fig. 4 of this discussion shows a cross section through these boilers, each of which is designed to generate 400,000 lb of steam per hr continuously at 875 psi and 900 F at the outlet of the superheater. The furnaces are of water-cooled construction, designed to burn either gas or oil. The contour of the water-cooled furnace makes it possible to adapt this furnace to pulverized-coal firing at some future date, if this becomes desirable.

² Application Engineer, The Babcock & Wilcox Company, New York, N. Y. Mem. ASME.

FIG. 4 CROSS SECTION THROUGH REDONDO STATION STEAM GENERATOR

The boiler and superheater tubes are arranged on wide centers to minimize tube fouling from oil-fuel slag. The first rows of boiler tubes are 4 in. OD on 18 in. centers, while the remaining three rows are 4 in. OD on 9-in. centers. The first bank of superheater tubes consists of $2\frac{1}{2}$ -in. tubes on 7-in. centers. The second and third banks of superheater tubes are $2\frac{1}{2}$ in. OD on $3\frac{1}{2}$ -in. centers.

The steam drum is 72 in. diam to provide water storage and space for water-level rise during quick load pickups. The steam drum contains cyclone separators and steam scrubbers so that the solids content of the steam leaving the boiler will not exceed 1 ppm even during sudden load pickup.

Steam temperature is maintained at 900 F from 250,000 to 400,000 lb of steam per hr by means of a shell-type attemperator connected between the first and second sections of the superheater through which a portion of the superheated steam will flow, giving up some of its heat to boiler water which circulates around the

outside of the tube bundle in the attemperator. The amount of steam that goes through the attemperator tube bundle is controlled automatically by a rotary valve. Quick response of temperature control is an important factor in steam-generating units designed for quick pickup of load.

The economizer is of the continuous-tube type, discharging into the steam drum through cyclone separators.

To facilitate the cleaning of troublesome deposits from superheater tubes, the floor under the superheater is arranged with a drain hopper so that the superheater surfaces can be washed with water during out-of-service periods. The economizer and air heater are also arranged so that they can be washed during out-of-service periods.

The expected efficiency of 81.41 per cent on gas fuel and 85.46 per cent on oil fuel have been exceeded on heat-balance tests which showed 82.24 per cent efficiency on gas, and 86.42 per cent efficiency on oil.

C. L. HATHAWAY.⁴ Mr. Chadwick has presented a very clear picture of the conditions in Southern California relative to the electrical demand in this area and to the facilities for meeting this demand. He has also brought to our attention many very interesting design details of the new Redondo Steam Plant. Of much interest is the method of controlling the growth of marine life in the circulating-water system, a very serious problem which the pioneering efforts of his company have solved successfully.

This discussion of Mr. Chadwick's paper will be limited to the following comments concerning the most southerly coastal portion of the area considered, that of San Diego. Several years before the war it became evident that the power facilities of the San Diego Gas & Electric Company would have to be expanded to meet the rising demand. This was due to the very great increase in the population of the area with its increase in domestic load requirements, to the rapid development and growth of the aircraft industry, and to the expansion of the needs of the United States Government. The company had at that time only one generating plant, Station B. This is a low-pressure steam station operating at 235 psi 700 F, located in downtown San Diego. Expansion of Station B was not advisable. The cost of increasing the circulating-water supply would have been prohibitive, and property values were comparatively high. A topping installation was considered, but the idea was abandoned because the load cycle did not lend itself well to this type of operation and because building alterations would have been excessive. In addition, any appreciable increase in the station's generation would have required extensive changes in the electric-transmission system in this area. For these and other reasons, it was deemed advisable to build a new station.

The site of the Silver Gate Station was chosen for several reasons; property values were reasonable, the station could be built near the San Diego Bay so that circulating-water problems would not be serious, and the location would be in a central part of the distribution system, with close proximity to the rapidly growing South Bay area.

Work was begun in 1941, and the station was placed in commercial operation in March, 1943. This plant consists of a 35,000-kw General Electric turbine, driving a 50,000-kva hydrogen-cooled General Electric generator at 3600 rpm. Steam is supplied at 850 psi and 900 F by two 200,000-lb per hr Babcock & Wilcox type F integral furnace boilers.

Before unit No. 1 was placed in service it was apparent that it would not be sufficient to meet the rapidly increasing load. Therefore, in December, 1941, the company placed an order for the second unit (50,000 kw). This was later canceled by government order so that all manufacturing facilities might be directed exclusively to further the war effort. It was not until late in 1945 that it was possible again to place orders. Work of installation was begun in 1946, and unit No. 2 was placed in service in April, 1948.

The delay in the installation of unit No. 2 due to the war, and the unexpected increase in load at the cessation of war activities, has made unit No. 3 an immediate necessity. Plant construction is now under way, and it is hoped that it may be placed in service early in the summer of 1950. This unit will operate at 1250 psi 950 F. This increase was deemed advisable in view of the increasing cost of fuel. Studies are now under way for unit No. 4, which will be the last at this site. Ultimate capacity of the station, based upon turbine ratings, will be 185,000 kw.

Fig. 5 herewith is an average of the actual week-day load conditions of the San Diego Gas & Electric Company for the month of January, 1949. This shows the peculiarities of loading in a comparatively small system in which the load is largely domestic.

⁴ Superintendent, Electrical Production, San Diego Gas and Electric Company, San Diego, Calif.

FIG. 5 AVERAGE DAILY LOADS ON WEEKDAYS, JANUARY, 1949

This load demand must be met by an all-steam system, as the company has no hydroelectric generating stations. Serious operating problems are introduced by the extremely high rate of load change, particularly when going from the minimum to the morning peak. This represents an increase of 150 per cent in $2\frac{1}{2}$ hr. This figure is not impressive if we consider the expected performance of a true stand-by plant; but it must be remembered that this is a daily occurrence and that a large part of this system pickup must be handled by the 99,000-kw low-pressure station, whose increase is in the nature of 500 per cent.

An explanation of the San Diego Gas & Electric Company's recent development in steam generation can best be made by describing Silver Gate unit No. 2. In listing the various items of equipment, comment will be made upon certain features which have been changed from the design of unit No. 1 and certain other points of interest.

The turbine is a General Electric 3600-rpm "Handbook" tandem-compound machine with double flow in the low-pressure section. It is rated at 50,000 kw with an overload rating of 25 per cent, or 62,500 kw. It was designed for and uses four points of extraction for feedwater heating. The hydrogen-cooled General Electric generator is rated at 60,000 kw at 80 per cent power factor (PF), or 75,000 kva. This rating is for $\frac{1}{2}$ psi hydrogen pressure. The main exciter is driven through a reduction gear coupled to the generator shaft and runs at 1775 rpm. It is a 220-kw 250-volt unit. The pilot exciter, a 4-kw 250-volt unit, is overhung from the end of the main exciter shaft.

Fig. 6 of this discussion is a heat balance for unit No. 2. The values shown are the turbine-generator manufacturer's estimates for a generator load of 62,095 kw (approximately $\frac{3}{4}$ turbine rating). This is a simple system with four-point regenerative feedwater heating. Generator hydrogen and exciter air are cooled by the full condensate flow from the hot-well pump. Condensate flow through these coolers and through the air-ejector condensers is increased during start-up, and at low loads by recirculation to the condenser. Make-up to the system is supplied by an evaporator receiving steam from the second turbine extraction point (10th stage) and discharging its vapor to the deaerating heater. The deaerator pressure is not held constant, but swings with that of the turbine third extraction point (14th stage) as load on the unit changes.

The turbine lubricating-oil system of unit No. 2 differs from earlier units in that there is no shaft-driven pump. Instead, there

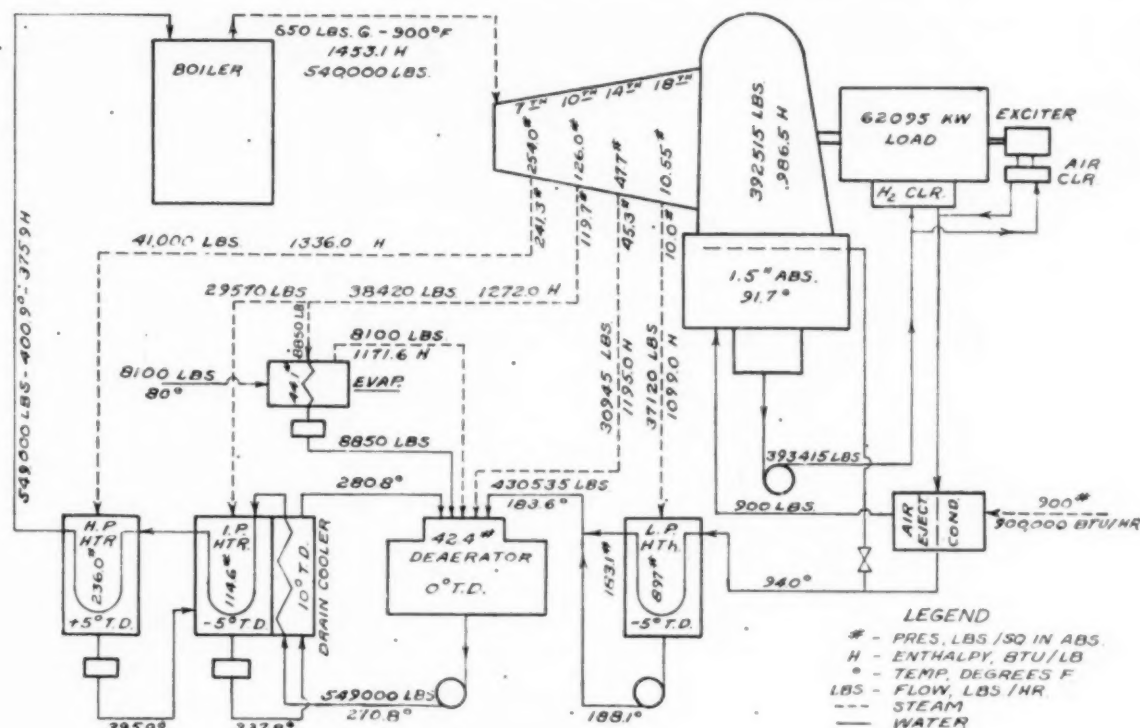

FIG. 6 HEAT-BALANCE DIAGRAM SILVER GATE UNIT No. 2
(60,000 kw, 3600 rpm, 0.8 pf, hydrogen-cooled generator, 850 psig, 900 F, 1 1/2 in. Hg abs.)

are two motor-driven pumps, so interlocked that the reserve pump will start on an outage of the preferred pump. There is also a steam-driven pump, which starts on low pressure, for emergency use. This pump rotates continuously at low speed, as a small amount of steam is fed through its turbine to keep it warm and available for immediate service.

The boilers of unit No. 2 are two Babcock & Wilcox integral furnace-type F which supply steam at 850 psi 900 F to the turbine. Each has a capacity of 300,000 lb per hr with an overload capacity of 10 per cent for 4 hr. As with unit No. 1, each boiler has two superheaters, with an externally mounted at-temperat in series between them. Considerable difficulty has been experienced with slag formation on the tubes of the unit No. 1 primary superheaters when oil fuel has been used. These deposits have been so heavy that actual bridging between tubes has resulted. This has caused excessive draft loss, requiring reduction in boiler load. The material on the tubes is hard and tough so that an extended outage is necessary to remove it mechanically. Use of natural gas as fuel tends to remove the deposit, but as gas is available only in certain seasons and then in limited supply, it cannot be depended upon to maintain cleanliness. Although the deposit is softened by water and is readily washed off, it has not been deemed advisable to water-wash these superheaters for fear of damage to the refractories and possible corrosion of the superheater headers and the boiler mud drum. For this reason the design has been changed for unit No. 2. The superheaters are of the pendant type with the headers above, and hoppers have been provided to drain off the wash water properly. It is felt that these superheaters can be quickly and effectively cleaned. In addition to this, the tube spacing in the primary superheater has been increased to 6 in. between centers, giving

much greater space for gas passage than in the older superheaters where tubes were spaced at 3 in. This has necessitated locating part of the primary superheater in the second gas pass of the boiler.

The waterwalls of the furnaces of the unit No. 2 boilers are the touching-tube type, instead of the stud-tube design of unit No. 1. This greatly reduces the amount of refractory required and increases materially the radiant-heat absorption. Boiler convection surface is reduced somewhat by the increased size of the superheater.

Boilers of both unit No. 1 and unit No. 2 are equipped with tubular air preheaters. The preheaters of unit No. 1 have horizontal tubes with the air on the inside and the gas on the outside. During the war period it was necessary to burn fuel oil with a comparatively high sulphur content. The resulting high-dew-point flue gas caused sufficient condensation on the cold-end tube sheet for chemical attack, so that a large number of the tubes were cut completely off at this point. In order to avoid this trouble in unit No. 2 preheater, the design was changed materially. The hot gases are on the inside of the tubes with the air outside. The preheater is divided into two sections, a main section and a short-tube cold-end section. It was thought that if high-dew-point conditions were again encountered it would be a simple matter to replace tubes in the cold-end section or, if necessary, alloy tubes might be used. As a further protection a cold-air by-pass was provided to control the cold-end temperatures at low load operation.

Both the forced-draft and induced-draft fans of unit No. 1 use vane control. Considerable trouble was experienced in the vane bearings of the induced-draft fans. Because of the high temperatures to which they were exposed the lubricant carbon-

ized and froze the balls in position, which resulted in operating difficulties and in high maintenance. Although this condition has been largely removed by the use of silicone lubricants, it was decided to use a different control for the induced-draft fans of unit No. 2. These fans are driven at variable speed through hydraulic couplings. Additional control is obtained by the use of dampers in the fan ducts.

Fuels used at Silver Gate are natural gas and industrial fuel oil Bunker D. In unit No. 1 this oil is delivered to the control valves at 280 psi. A centrifugal pump which maintains constant differential of 100 psi between the burner supply and return, raises this to about 350 psi at maximum demand. For unit No. 2, centrifugal booster pumps raise the pressure to 660 psi at the control valves, and a 250 psi differential is maintained at the burners, giving a full-load maximum of about 900 psi. This increase in fuel-oil pressure is to permit the use of smaller burner tips and thus to obtain better atomization and better combustion at low loads. It is planned to convert unit No. 4 to the same pressure levels, and a comparable change will be made at Station B.

Fuel-oil storage is by three steel-lined concrete tanks located beneath the 12.5-kv substation structure. Each tank has a capacity of approximately 5300 bbl, with a normal net of a little over 4000 bbl. Delivery to these tanks is by pipe line from the oil company's tanks or direct from tankers. The storage afforded by these tanks is not deemed adequate, so it is planned to provide an 80,000-bbl tank for additional reserve.

High-pressure steam piping in unit No. 2 uses welded joints throughout. All joints were checked by gamma ray. This is a change from unit No. 1 piping where octagonal ring-flanged joints are used.

Bearing and jacket cooling at Silver Gate is supplied by fresh water. This is a closed system, common to both units, in which

city water is circulated through salt-water heat exchangers. The fresh water is treated to maintain a noncorrosive condition. Make-up to this system is by condensate drains, so that the solids concentration is less than that of the city water. The only use of salt water is in these exchangers and in the main condensers.

Fig. 7 herewith is a diagram showing the station's hookup with the distribution system. Electric generation is at 12,500 volts. Each generator feeds a ring bus which is connected on one side to the two main buses of a 12.5-kv substation, and on the other to the transformer banks for the 69-kv system. Station auxiliaries for each unit are supplied at 2400 volts by two transformers, one from the generator bus and one from a feeder from the 12.5-kv substation. The larger units operate at 2400 volts, the smaller ones at 220 volts.

The Silver Gate Station is not of the outdoor or semioutdoor type, in that both the turbine and boiler rooms are enclosed. The partially open type of plant was considered, but the advantages of the closed building were believed to more than offset its increased cost. It might be well to mention a few of the points considered in making this decision. A slight increase in operating efficiency results from the partial recovery of radiation heat losses. This is effected by placing the forced-draft fans on the top floor of the boiler room. Next, it is possible to do maintenance work in any part of the plant on short notice, regardless of weather conditions. This is of considerable importance in a small all-steam system, such as that of the San Diego Gas & Electric Company. Further, morale of the operating personnel is definitely better with the closed plant. This is a point that is always considered but usually not credited with sufficient importance. There are other advantages to the enclosed station; such as, greater ease in maintaining plant cleanliness, less chance of neglect of routine operating duties, etc.

FIG. 7 SILVER GATE STATION HOOKUP WITH DISTRIBUTION SYSTEM

TABLE 3 PRINCIPAL POWER-PLANT EQUIPMENT AT SILVER GATE STATION UNIT NO. 2

TURBINE GENERATOR UNIT	
Turbine.....	General Electric Company
50,000 kw, 3600 rpm, tandem-compound, double-flow, condensing steam turbine 850 psi, 900 F, 1 1/2-in. exhaust; 4 bleed points.	
Generator.....	General Electric Company
60,000 kw, 0.8 pf, 12,500 volt, 3 phase 60 cycle, hydrogen cooled. Main exciter direct connected through reduction gear, 1775 rpm, 220 kw, 250 volt, pilot exciter 4 kw, 250 volts.	
Condenser.....	Worthington Pump & Machinery Corporation
Two-pass, divided water box, surface type with 40,700 sq ft effective surface. Tubes are of arsenical aluminum brass, tube sheets of rolled muntz metal.	
Circulating-water pump.....	Worthington Pump & Machinery Corporation
Two 36-in. vertical, 21,000-gpm, 390-rpm, motor drive, 150 hp, 2300 volts.	
STEAM-GENERATING EQUIPMENT	
Boilers.....	Babcock & Wilcox Company
Two integral-furnace type, 875 psi 900 F 300,000 lb per hr; overload capacity 330,000 for 4 hr. Heating surface, boiler and furnace: 21,500 sq ft superheater, pendant type, three steam passes. Temperature control by external attenuator.	
Air preheater.....	Babcock & Wilcox Company
Vertical tubular, 2 sections, 2 gas passes, gas in tubes, 3 air passes. Heating surface 44,674 sq ft.	
Forced-draft fans.....	Buffalo Forge Company
One per boiler, 101,000 cfm at 120 F, 1180 rpm, variable vane control.	
Induced-draft fans.....	Buffalo Forge Company
One per boiler, 181,000 cfm at 435 F. Control is by variable-speed drive through hydraulic coupling, and dampers.	
Fuel burners.....	Peabody Engineering Company
Four per boiler, type H-26, combination gas and oil. Oil burners are wide-range mechanical-atomizing with constant differential of 250 psi, and a maximum top pressure of 900 psi.	
Safety valves.....	Crosby Steam Gate & Valve Co.
Three per boiler, 4 in.	
Combustion control system.....	Bailey Meter Company
Fuel flow-air flow on both fuels; temperature control.	
CONDENSATE AND FEEDWATER SYSTEM	
Condensate pumps.....	Worthington Pump & Machinery Corporation
Two 3-stage 1183 rpm, 963 gpm	
Feedwater heater No. 1.....	Foster Wheeler Corporation
Low-pressure, vertical, 4-pass, 1915 sq ft surface. Steam from 18th stage extraction.	
Feedwater heater No. 2.....	Cochrane Corporation
Deaerator, 750,000 lb per hr, storage capacity 124,000 lb. Steam from 14th stage extraction, evaporator vapor, etc.	
Feedwater heater No. 3.....	Foster Wheeler Corporation
High-pressure, vertical, 4-pass, 2506 sq ft surface; has drain cooler section. Steam from 10th stage extraction.	
Feedwater heater No. 4.....	Foster Wheeler Corporation
High-pressure, vertical, 4-pass, 2206 sq ft surface. Steam from 7th stage extraction.	
Evaporator.....	Foster Wheeler Corporation
Type H.P., single effect, with preheating and degassing section. Capacity 12,000 lb per hr. Pressures: coils, 250 psi; shell 50 psi.	
Boiler feed pumps.....	Ingersoll-Rand Company
Three 850 gpm, 3568 rpm, 2880 ft total head, motor-driven, barrel-type casing.	
Feedwater regulators.....	Bailey Meter Company
Three-element control.	
PIPING, VALVES, AND FITTINGS	
Piping contractor.....	Midwest Piping & Supply Co.
Main steam line.....	Chrom-moly ASTM A-280-46T
Main steam valves.....	Crane Company
Stop-check valves.....	Edward Valve Company
Blow-off valves.....	Edward Valve Company
Boiler feed pump check valve.....	Chapman Valve & Mfg. Co.
Small high-pressure valves.....	Edward Valve Company
Steam traps.....	Henry Vogt Machine Company
	Armstrong Machine Works
	Yarnall-Waring Company
ELECTRICAL EQUIPMENT	
Main transformers.....	Westinghouse Electric Corp.
Two TCUL, 12.5/69 kv	
25,000 kva	
Station transformers.....	Westinghouse Electric Corp.
Two 12.5/2.3 kv, 4500 kva	
Station auxiliary transformers.....	Pennsylvania Transformer Co.
Two 2400/240 volt, 750 kva	
Station lighting transformers.....	Kuhlman Electric Company
Two 2400/240/120 volt, 200 kva	
Generator oil circuit breakers.....	Kelman Electric & Manufacturing Company
Two 15 kv, 3000 amp	
2400-volt switchgear.....	General Electric Company
Indoor type, metal clad	
220-volt power centers.....	ITE Circuit Breaker Company
Motors:	
Boiler feed pump.....	Westinghouse Electric Corp.
Fans.....	General Electric Company
Circulating-water pumps.....	Westinghouse Electric Corp.
Hot-well pumps.....	Westinghouse Electric Corp.
Compressors.....	General Electric Company
MISCELLANEOUS EQUIPMENT	
C.W. traveling screens.....	Chain Belt Company
Control air compressors.....	Ingersoll-Rand Company
Heater drain pumps.....	Ingersoll-Rand Company
Fuel-oil booster pumps.....	Byron Jackson Company
Sump pumps.....	Yeomans Brothers Company
Differential oil pumps.....	United Iron Works

The Silver Gate plant is a windowless building except for the office bay. Air is supplied by a ventilation system which takes in outside air at the top-floor level. This gives a supply of fresh air to the station more nearly free of dust than would be provided by windows or louvers at near street elevation.

As a one-unit plant, the Silver Gate Station was operated by a four-man crew, in addition to a part-time electrician. This consisted of one engineer, one fireman, and two auxiliary engineers. When unit No. 2 was placed in service an additional fireman was provided, bringing the total to five men.

The engineer, in addition to his duties as turbine operator, handles all the electrical operations frequently performed in a separate control room. Synchronizing and breaker operation are controlled at the turbine-generator panel. This of course does not include operation of the substation which is by supervisory control by the system load dispatchers.

Table 3 gives a list of the major equipment of Silver Gate Station unit No. 2.

B. G. HUME.⁵ The City of Los Angeles' Harbor Steam Plant is located adjacent to the Los Angeles Harbor. This plant was designed, built, and is operated by the Department of Water and Power, a municipally owned corporation serving the 450 square-mile area within the limits of the City of Los Angeles. This location was selected for a plant site as it afforded an ample supply of cooling water for a plant of large capacity, combined with proximity to the center of the city's industrial load.

Studies made in 1939, of the anticipated growth of load on the system, indicated that it would be necessary to add additional

⁵ City of Los Angeles, Department of Water and Power, Los Angeles, Calif.

steam-generating capacity to the system by about 1943. This study of system requirements indicated that more stand-by steam power would be needed in the form of spinning reserve, and that this type of operation probably would change to base-load operation as the number of steam units on the system increased. Therefore it was decided to build a new steam plant, the first two units of which would provide spinning reserve and, when required, carry system peaks or base load.

Accordingly, orders were placed for two 81,250-kva units, the first to go into operation in 1943, and the second about a year later. The war interfered with this program, however, and the second unit did not go into operation until late in 1947.

By 1946 it became evident that unless considerable additional generating capacity was added as soon as possible, there would be a power shortage in Los Angeles. Orders were then placed for three additional units having a capacity of 93,750 kva each.

The curves in Fig. 8 of this discussion show the growth of load in terms of kilowatthours generated and kilowatt peak, respectively. These curves are extended beyond the year 1948, showing the probable growth of the load on the Department's system to and including the year 1952. Unit No. 2 was completed in November, 1947, just in time to prevent a serious power shortage on the system. Likewise, units Nos. 4 and 3 were completed in December, 1948, and February, 1949, respectively, in time to enable the department to help alleviate the shortage of power in California.

There are five turbine-generator units now installed in this plant. The fifth unit will go into service in the near future. This will complete the plant to its ultimate rated capacity of 355,000 kw on the main units. Unit No. 1 and unit No. 2 each consists of a 65,000-kw, 0.8-power factor (pf), 3600-rpm tandem-compound

FIG. 8 POWER SYSTEM OF THE CITY OF LOS ANGELES DEPARTMENT OF WATER AND POWER

turbine connected to a 81,250-kva, 60-cycle, 3-phase, 13,800-volt hydrogen-cooled generator. Units Nos. 3, 4, and 5, each consists of a 75,000-kw, 0.8-pf, 1800-rpm, single-cylinder turbine connected to a 93,750-kva, 60-cycle, 3-phase, 13,800-volt hydrogen-cooled generator. The nominal steam pressure and temperature at rated capacity is 850 psig and 900 F. Each turbine exhausts into a twin condenser, consisting of an exhaust trunk connected to the turbine exhaust which divides the steam and discharges it into two one-half size condensers located on either side of the foundation. This design permits low center of gravity and low siphon leg on the cooling-water outlet.

Circulating water is supplied to each twin condenser unit by two vertical mixed-flow pumps driven by vertical splash-proof motors.

The plant requires approximately 300,000 gpm cooling water. This water is taken from slip No. 5 of the harbor by means of two 8-ft-diam precast concrete pipe tunnels 1200 ft long and discharged into the West Basin through two similar tunnels approximately 1400 ft long. The temperature of the water varies from 55 F in the winter to 70 F for a short period of time in the summer.

Each turbine is supplied with steam from one steam-generating unit. The first two boiler units installed have a rated capacity of 570,000 lb of steam per hr and a 2-hr overload capacity of 760,000 lb per hr. The remaining three steam-generating units have a continuous rating of 650,000 lb of steam per hr, with a 2-hr overload rating of 825,000 lb per hr. These units are equipped to burn oil and gas and can be converted to burn pulverized coal at reduced rating if it should be necessary to burn the latter fuel at some future time.

All auxiliaries are motor-driven except for the emergency boiler feed pumps which are driven by steam turbines. The cycle is a straight regenerative cycle with four extraction points.

Horizontal feedwater heaters are arranged vertically, one above the other in the auxiliary bay, to provide positive drainage at low loads and to take care of surges when the load is suddenly increased.

As the first two units were to be designed for either base-load, peaking, or stand-by service, they would have to be capable of carrying the least possible load when there was plenty of hydroelectric power available and to pick up full maximum load instantly at the time of an outage and carry it until such time as the system might be restored to normal, or to carry a base load for protracted periods of time during dry years or whenever the system load exceeded the capacity of the hydroelectric plants. For the latter reason, these two units were designed for good econ-

omy when operating on base load. The wisdom of building economy into this type of plant has been proved during the past power shortage, as it was necessary to operate most of the time on a base load. The performance of 10,900 Btu per net kw-hr at the most efficient load has been realized from these units.

When it became necessary to add the last three units, it was decided to eliminate the extreme requirements for stand-by operation, imposed on the first two units, by eliminating the excess fan and fuel-burning capacity built into the first two units. While the last three units afford considerable stand-by power, if required, they have not been designed for the very low load operation. This was considered unnecessary because of the greater proportion of steam to hydroelectric power existing at the later date.

Units Nos. 1 and 2 have been designed to operate on a minimum block load of 5000 kw indefinitely and, when the occasion demands, assume full rated load instantly. In order to accomplish this result, it was necessary to provide the following features in the design of the plant:

- 1 Absolute minimum carry-over in the steam under all conditions of operation.
- 2 Wide-range burners.
- 3 Positive, fast-acting fan control over a wide range.
- 4 Positive superheat control over a wide range.
- 5 Positive, fast-acting automatic combustion control
- 6 Positive heater drainage at all loads.
- 7 Automatic boiler feed pump control.

The boilers were designed for a minimum water-storage capacity of 3500 cu ft. The controls were designed to maintain a constant steam pressure in the steam drum. A dry drum was provided to prevent carrying over of any quantity of water to the turbine during periods of quick pickup and also to prevent carry-over of solids into the superheater and turbine during normal operation. This design provided maximum heat storage in the boiler and maximum steam pressure at the throttle when the unit was operating on stand-by load.

The fans and burners were designed to have about one and one-half times the required full-load capacity in order that the unit could be fired at a rate high enough to enable the boiler to supply steam for the highest possible quick-pickup load and at the same time recover full steam pressure in the least possible time.

These requirements made it necessary to install oil and gas burners having a maximum range of 15 to 1, and fan drives that could control the speed of the fans accurately enough for the automatic combustion control to function properly when the unit is carrying a 5000-kw load. At the same time, these fan drives had to be able to increase the rate of firing the boiler fast enough to enable the turbine to assume full rated load instantly without permitting the steam pressure at the throttle to drop lower than 750 psig. Motor-generator sets with a modified type of Ward-Leonard control were the only system of fan drives available that would meet these specifications. The turbines are designed to carry rated load on the minimum steam pressure and are provided with a minimum steam-pressure load-limiting device that will cut back on load should the steam pressure fall below this value.

Should an outage occur, the turbine is released automatically from the low block and instantly assumes approximately full rated load. This load is limited by the high-block limit device. The steam pressure in the boiler drum immediately begins to drop. The fans come up to the full speed and the fuel valve opens wide. Fuel is then fired to the boiler until steam pressure is restored to normal for the corresponding load. As soon as equilibrium is restored, the high load limit is moved out of the way and

the turbine generator can take load up to its maximum capability.

Results of tests on the system show that the fuel valve opened wide in about 8 sec, and the fans came up to speed in 10 sec. During this time the steam pressure dropped from 1040 psig to 770 psig. The steam pressure then began to rise until full operating pressure was restored in 8 min. It was not possible to duplicate exactly an actual system outage. Hence the load pickup to 48,000 kw instantly, and to 58,000 kw in 40 sec was somewhat slower than would be the case should a system outage occur.

Units 3, 4, and 5 depart from standard practice in one important respect, namely, the regulation of feedwater by controlling pump speed. Feedwater control in units Nos. 1 and 2 is accomplished by means of a conventional throttling feedwater regulator. At low loads this results in extremely high pressures in the feedwater system on the discharge side of the pumps. It also results in a considerable waste of power at all loads. Economic studies indicated that the power saved by installing variable-speed hydraulic drives would justify the additional cost, and expensive boiler-feed regulating valves could be eliminated. Furthermore, intangible savings in maintenance could be effected by eliminating the high excess pressure on piping valves and heaters.

The speed of the pumps is regulated by the boiler's demand for feedwater. This means of control is very stable and no trouble has been experienced in regulating the level of the water in the drums in this manner.

E. H. KRIEG.⁶ To have constructed such an unusual station as Redondo in less than 18 months would have been a good record under any conditions, but the author has good reason to tell of the achievement so that others may know what can be done.

The design and construction of a power plant on the seashore is indeed a challenge, and the response to that challenge has been unusual in the development of reversal of circulating water for control of mussels and marine organisms in the circulating water system. The average power-plant operator has a healthy respect for what happens when the flow of water in even small-diameter short-length feedwater lines is stopped even without being reversed, but when the designer and operator must think in terms of 10-ft-diam tunnels that are each 1900 ft long, it takes courage and keen imagination to anticipate the many conditions which can arise to avoid the large losses in investment and outage that anything else but complete success would entail.

No doubt an entire paper could be written on the ingenuity called for in arranging for such quick load pickup, from 5 per cent to full load in 15 sec, particularly when many operators ordinarily try to follow turbine-loading rates of perhaps 5 per cent of rating per min even when no steam-temperature change is involved. Further to plague the designer was the need of providing earthquake protection, not only in the structure but to insure that heavy masses would not start swinging out of phase with other lighter masses to which they are connected. This refers particularly to the intricate problems involved in supporting and damping the vibrations in various parts of a piping system where a relatively light steam line is connected to a heavy nonreturn valve or a heavy turbine emergency stop valve that may weigh 5 or 6 tons.

Now that there are no great hydroelectric developments like Hoover Dam on the horizon to augment system capacity, the author states that future capacity is to be steam-driven. Fuel costs of 30 cents per million Btu are high to one accustomed to thinking in terms of 15 or 20 cents. This naturally develops the thought, expressed by the author, that the reheat cycle has a

great deal to offer. This is particularly true of a system which has a great deal of steam-turbine-driven capacity, 20 years old and more, that is so economical for handling short-time peaks overlying a broad base of capacity to be supplied by very efficient units. In other words, where 35 per cent load factor had been commonly associated with steam units, a base is now beginning to develop where steam units in the future will have load factors of 60 per cent and over, even if the full-term life of the unit is taken into account.

High fuel costs point the way toward more efficient units, offering a temptation to go to higher pressures and temperatures. High temperature is the element much more likely to place a limit on quick load pickup which is so important to the system. Reheat is fundamentally more conservative than the higher temperatures for an equivalent heat rate. For example, the reheat cycle is equivalent to approximately 150 F higher temperature in a straight regenerative cycle, and there is little doubt that a 950 F—950 F reheat cycle is more conservative than an 1100 F regenerative cycle at the present time.

When oil is the major fuel, high steam temperatures must be looked at carefully, if not askance, to avoid the very serious wastage of exterior surfaces of tubes caused by vanadium pentoxide which has given so much trouble when used with tubes having external skin temperatures over 1100 F.

The judicious use of partial outdoor construction shows an appreciation of the advantages and also the limitations that such a layout affords. Where salt fogs are possible, protection against condensation in electrical equipment must be provided.

Because Hoover Dam played such a large part in supplying the electricity needs of Southern California during the last two decades, considerable foresight and ingenuity should characterize the decisions to be made on capacity additions during the next decade as they will be mostly of the steam type. Further, the new plants must anticipate burning coal as well as utilizing gas and oil while it is still available. That this challenge is clearly recognized is evidenced by the author's statement: "With an expansion of 760,000 kw in steam-generating capacity either constructed or in progress since the end of the war, the power systems of Southern California are determined that power supply to that area shall be in time and enough."

AUTHOR'S CLOSURE

Each of the discussions includes many interesting items which were not covered by the author and which add to the value of the paper. Mr. Gilg has described the features of the steam-generating equipment at Redondo most capably. Messrs. Hathaway and Hume have presented excellent discussions of Southern California generating stations whose basic characteristics were determined by the general conditions mentioned in the author's paper, but which have individual features of design which were influenced by local conditions and preferences. Mr. Hathaway has included an able presentation of the arguments favoring the all-indoor station. However, these arguments should be balanced against the savings in construction costs of several dollars per kilowatt which are possible with semioutdoor construction. Mr. Krieg's broad experience in the design of steam-electric generating stations makes his discussion particularly welcome. His comments on the advantages of the reheat cycle are especially pertinent.

The downward trend in Southern California fuel prices, which was mentioned in the paper, has continued. As of October 20, 1949, gas is 16.0 cents per million Btu and fuel oil is 20.6 cents per million Btu. There has been no significant change in the estimated cost of coal.

The increased importance of steam power throughout the Pacific Southwest (Arizona, California, and Nevada) is shown by

⁶ Consulting Engineer, Stone & Webster Engineering Corporation, Boston, Mass. Fellow ASME.

the change in margin between installed hydro capacity and the maximum demand. Prior to 1940, under favorable water conditions, it would have been possible to carry the maximum demand of the area on the available hydro generation. By 1948, in spite of the addition of nearly 1,000,000 kw of hydro capacity, the demand was 1,400,000 kw more than the total installed hydro capacity.

In the Southwest in 1940 only 11 per cent of the power was generated by steam, whereas in 1948 steam power produced 38 per cent of the kilowatthours for the area. The increases in demand since the war, and the further increases which are forecast in all estimates of future demands, indicate increased dependence on steam power for base-load generation throughout California and the Pacific Southwest.

FIG. 10 COMPLETED REDONDO STEAM STATION, REAR VIEW

Postwar Planning for Steam Capacity in Northern California

By C. C. WHELCHER¹ AND W. R. JOHNSON,² SAN FRANCISCO, CALIF.

The estimated population for northern and central California on January 1, 1949, was 4,950,000. This represents an increase since 1940, of 1,667,000 or about 51 per cent. The Pacific Gas and Electric system peak in 1940 was 1,125,000 kw. In December, 1948, it was 2,050,000 kw under daylight-saving time. Standard time would have added 160,000 kw. If the current trends continue, it is estimated the peak in 1951 will be 2,633,000 kw. Planning the required steam-generating capacity to carry its proper share of this unprecedented load growth is discussed in this paper.

INTRODUCTION

THE northern and central part of California served by the Pacific Gas and Electric Company comprises an area of approximately 90,000 square miles with a population approaching 5,000,000. Along with other sections of the West Coast, this area is experiencing an unusual postwar growth in population, in industry, and in the general level of business and agricultural activity. This growth is reflected in the increasing electric power load, and by the current construction program of the authors' company, under which nearly 1,300,000 kw of new hydroelectric and steam-electric generating capacity will be added to the resources of the area before the end of 1951.

The purpose of this paper is to present the background leading up to this current expansion program, to discuss reasons for the location and amounts of steam capacity being added to the system, and to explain unusual technical features of these new plants.

LOAD GROWTH AND POWER SUPPLY

The territory served with electric power largely by the Pacific Gas and Electric Company is a naturally coherent geographical area nearly 500 miles in length, and between 150 and 200 miles in width. The heart of this region is the great valley of the Sacramento and San Joaquin Rivers, bounded by the Sierra Nevada on the east, by the coast ranges on the west, and by other mountain groups on north and south. The natural outlet for the valley, both geographic and economic, is through the San Francisco Bay region.

In Fig. 1 certain features of this territory are shown, including its main watercourses, and location of the company's hydro and steam-electric power plants. The hydro plants, with minor exceptions, are scattered along the western slopes of the Sierra Nevada. They are located on many different rivers, progressing from the Pit in the north, down along the Feather, Yuba, Bear, American, Mokelumne, Stanislaus, San Joaquin, Kings, and finally the Kern River in the extreme south. Hydro developments by others are not indicated; notable among these omissions are the

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-SA-10.

FIG. 1 TERRITORY SERVED BY THE PACIFIC GAS AND ELECTRIC COMPANY

(The scale for this map is roughly 1 in. to 100 miles.)

Big Creek development on the San Joaquin by the Southern California Edison Company, Ltd., the Shasta and Keswick powerhouses of the United States Bureau of Reclamation, the City and County of San Francisco plants on the Tuolumne, and various irrigation district projects.

Steam-electric plants are indicated by solid triangles. They are located in the San Francisco Bay region, along the coast, and in the extreme southern part of the territory. Plants built, or under construction, in the postwar expansion program are indicated by a double triangle.

After a brief decline in the early 1930's, the consumption of electric energy has climbed steadily upward. This is shown by the curves of annual peak kilowatts and energy in Fig. 2. During the war years growth was accelerated. As the peak of war activity passed there appeared to be a slight decrease in the rate of growth, particularly in 1945 and 1946. It was commonly anticipated, by business and government alike, that a return to prewar

FIG. 2 ANNUAL PEAK KILOWATTS OF LOAD AND ENERGY OF PACIFIC GAS AND ELECTRIC COMPANY SYSTEM

trends would occur. The incorrectness of this reasoning is clearly indicated by the load growth experienced in 1947 and 1948. The system peak of 2,078,900 kw in 1948, represented an increase of 9 per cent over the 1947 peak; while 1947, showed an increase of 13 per cent over 1946.

From 1940, the last prewar year, to 1947 inclusive, peak demand increased from 1,125,700 kw to 1,906,200 kw. This increase of 780,500 kw in 7 years is a growth of 69 per cent, or an average yearly increase of approximately 8 per cent.

In this same period the Pacific Gas and Electric Company brought 206,000 kw of hydro capacity and 100,000 kw of steam capacity into operation, a total addition of 306,000 kw. Also the United States Bureau of Reclamation brought into operation two units at Shasta Dam with a name-plate rating of 150,000 kw. The additions by the power company were projects well started and equipment largely manufactured prior to the war. Exceptions were 32,000 kw of peaking capacity at Pit River No. 1, obtained by enlarging forebay capacity for existing units, and two small steam units in the Eureka area in 1946-1947. Orders for two large steam units placed prior to the war in 1941, were held in abeyance in the interest of the over-all national defense program. These orders were reinstated at the end of the war, and both units went into operation during 1948—seven years after the original orders were placed.

In addition to the two large steam turbogenerators and the smaller installations, just mentioned, planning for other new generation was pursued vigorously as the war period drew to a close. The program, however, faced serious delays beyond the company's control. Manufacturers found themselves swamped with orders for major equipment items; the wave of labor difficulties delayed production. Furthermore, the vagaries of nature brought subnormal rainfall during 1947, followed by the driest January and February, on record in 1948.

In spite of the most strenuous efforts by the company, the effects of drought in reducing hydrogeneration and greatly increasing the agricultural irrigation pumping load, made necessary a power-curtaillment program. This period was of short duration

owing to the combined effects of daylight-saving time, heavy spring rains, power delivered from southern California, and completion of new plants in northern California. The new plants brought into operation at this time were the first major units completed in a postwar program of considerable magnitude.

THE POSTWAR PROGRAM

A construction program of great magnitude is now well under way to restore adequate power margins and to serve the rapidly growing needs of the area. The estimated net generation capacity increases, constructed and planned for the 1946-1951 period, are given in Table 1.

TABLE 1 ESTIMATED NET GENERATION CAPACITY INCREASES—1946-1951

	Steam, kw	Hydro, kw	
1946-1947	Two additional units, boilers and improvements to existing plant in the Eureka area (approx).....	Pit River No. 1 forebay peaking increase on existing units.....	32000

	Contra Costa.....		
	Contra Costa.....		
	Total steam.....		987000

^a Replaces existing generation at the two plants totaling about 30,000 kw.

This program was decided upon after consideration of many factors relating to the amounts of steam and hydro capacity to be added. The basic reasons for the large proportion of steam generation include the following:

1 Steam-capacity additions postponed by the war. The first units at Kern and Hunters Point are in this category. These steam-capacity additions had been planned prior to the war as necessary to maintain the desirable steam-hydro ratio in the area.

2 Steam capacity required because of the changing economic steam-hydro ratio. The economic and other factors entering into the optimum proportions of steam and hydro capacity have been discussed fully in earlier papers. As the more favorable hydroelectric sites are developed,^{3,4} those remaining are more costly. At the same time technological improvements in steam-plant design, such as larger unit size and higher efficiency, have tended to reduce the relative cost of steam. Offsetting this has been a rising fuel cost. However, the over-all result has been a gradual shifting of the economic steam-hydro ratio from approximately 75 per cent hydro and 25 per cent steam to nearly equal amounts of each.

This trend is illustrated in Fig. 3, which shows the annual energy sources for the company's system from 1930 on, in per cent of the total for each year. The energy shown coming from "other sources" is almost entirely from hydroelectric plants owned by others. The proportion of energy from fuel plants is as low as 3 per cent in 1935, and is seen to be increasing gradually, reaching 36 per cent in 1947. However, the trend is partially obscured by the effect of variations in precipitation, both 1947 and 1948 being below average. In such years the amount of steam energy is much greater than normal.

3 Steam capacity for support of hydro developments planned by the company after 1951.

³ "Aspects of Steam Power in Relation to a Hydro Supply," by A. H. Markwart, *Mechanical Engineering*, vol. 48, 1926, pp. 557-561.

⁴ "Mingled Hydro and Steam Power Production in California—Past, Present, and Future," by A. H. Markwart, *Trans. AIEE*, vol. 59, 1940, pp. 775-781.

FIG. 3 ENERGY SOURCES FOR THE PACIFIC GAS AND ELECTRIC COMPANY SYSTEM

4 Factors in planning and construction. Nearly all new hydro developments require procurement of licenses and water rights involving Federal agencies and other interests. Until satisfactory agreements are reached on these matters, design and manufacture of the major equipment cannot be commenced, nor preliminary construction begun.

Steam turbogenerators, on the other hand, do not have their design dictated by the site where they are to be installed. Therefore, orders may be placed and design commenced far in advance of the procurement of a satisfactory site.

5 The company has always followed a policy of planning to facilitate the absorption of hydroelectric energy produced by irrigation districts, the United States Bureau of Reclamation, and other agencies as a by-product of water-conservation projects. The prime importance of development and best use of California's water resources have long been recognized. The company endeavors to co-operate to the utmost in the utilization of incidental power from these projects for the greatest possible benefit to the project.

SYSTEM INFLUENCES ON STEAM-PLANT LOCATIONS

With some artistic liberties, the problem of load and power supply on the company's system for an estimated average water year, as of 1951, is shown in Fig. 4. Energy from hydroelectric sources is represented by the unshaded arrows, that which must be supplied from steam plants by shaded arrows, and the quantity of energy involved is proportional to the arrow width. It is rather apparent that major steam plants should be located in the southern and west-central portions of the area if transmission losses are to be minimized.

Planning for steam plants of the capacities needed for this program required consideration of factors not involved in smaller installations located in metropolitan areas where power may be fed directly into the distribution network. It is not feasible on the company's system to take away the full output of a large plant entirely over distribution voltage circuits, nor can the large blocks of generated power be absorbed locally at periods of light load.

In view of the foregoing the new plants were designed for system, as well as local area use, and it was necessary in each case to provide full-capacity outlets directly to the transmission system. With such outlets the general plant locations were determined after considering such factors as area power supply and load, availability of fuel, make-up water, condenser circulating water, foundation conditions, transmission outlets, and the possibility of future expansion.

All four of the new large steam plants required construction of high-voltage transmission connections. This was accomplished for Hunters Point by means of 115-kv underground-cable connections to a transmission substation in combination with power sup-

ply to a new 115-kv distribution substation in downtown San Francisco. The Kern plant connects directly to the 115-kv transmission by overhead lines to substations in the vicinity, and is provided with transformer auto taps to feed into the 70-kv subtransmission. At Moss Landing two of the units will have auto tap connections tying into the 115-kv transmission lines, in the area, but all three units will have full-capacity outlet by 230-kv lines to the San Joaquin Valley and the lower San Francisco Bay regions. While the other plants have connections to the 115-kv or subtransmission, the entire output of the Contra Costa plant will be transmitted over the 230-kv high-voltage network.

KERN STEAM PLANT^{5,6}

Agriculture has long been recognized as the basic industry in California and the one which in a large measure is responsible for the prosperity of the state. The San Joaquin Power Division of Pacific Gas and Electric Company, with headquarters at Fresno, represents over 70 per cent of the system's agricultural load. In 1946, the peak for this division was 415,000 kw. In 1948, it was 578,000 kw. The estimate for 1951, based upon present trends is 800,000 kw, which represents a 93 per cent increase above 1946, a 5-year period.

⁵ "Control is Centralized at Kern station," *Electrical World*, vol. 130, Sept. 25, 1948, pp. 90-91.

⁶ "Centralized Control at Kern," *Electrical West*, vol. 101, 1948, pp. 79-80.

FIG. 4 ESTIMATED LOAD AND POWER SUPPLY FOR THE PACIFIC GAS AND ELECTRIC COMPANY SYSTEM IN 1951, WITH AN AVERAGE WATER SUPPLY

(The scale for this map is roughly 1 in. to 100 miles.)

FIG. 5 KERN STEAM PLANT

In the lower end of this territory, power had been supplied from transmission sources, small hydro and steam plants, and from an interconnection with the Southern California Edison Company at Magunden. Upon termination of the Edison Company's interchange agreement in December, 1947, a replacement of this power source was required. Additional steam capacity in the Bakersfield area proved to be an economical means of replacing this supply, as well as providing for a portion of the load growth in the lower San Joaquin Valley. Since there are no rivers in the area capable of supplying condenser circulating water, cooling towers must be used, and their make-up is supplied by wells. The use of cooling towers permitted the plant to be located on a level 160-acre plot near oil refineries which supply fuel oil by pipe line. To those not accustomed to obtaining condensing water in this manner, it may at first seem strange to locate a large steam power station in an open field. That, however, proved to be most suitable for this station which is 5 miles west of Bakersfield on the Santa Fe Railroad.

The first main unit at Kern, which is rated at 75,000 kw, has been in commercial operation since May 10, 1948. A 100,000-kw second main unit is scheduled to be placed in operation during January, 1950. There will be two accompanying house units of 6000 and 7500 kw, respectively. Each of the four boilers has a normal full-load evaporation rate of 450,000 lb of steam per hr. These boilers are designed to burn either fuel oil or natural gas. A general view of this plant is shown in Fig. 5.

MOSS LANDING STEAM PLANT

Another important agricultural center, sometimes called the "Salad Bowl of America" because of its tremendous production of lettuce, celery, and artichokes, is located along the coast of Monterey Bay, with much of the business activity centering at Salinas. The agricultural lands here must also be irrigated by water pumped from wells. In this area at Moss Landing, a 270-acre site was selected as the location of a new plant in which three 100,000-kw main units and three 7500-kw house units will be installed initially. As in the other stations, two boilers per turbine have been provided. An appreciable amount of the power from this plant will be used locally with much of the remainder normally being transmitted east over the coast range mountains to the San Joaquin Valley in the general areas of Fresno and Bakersfield.

Condenser circulating water will be drawn from Moss Landing Harbor and discharged into Elkhorn Slough to the north. Since

Elkhorn Slough is connected to the harbor, a careful study of the possible effects of recirculation was undertaken. It was concluded that while certain conditions of unfavorable tidal flow may result in some temperature elevation, this will occur infrequently and should not affect the capacity of the first three turbines. Operating experience with the initial installation will determine what, if any, further precautions must be taken when additional units are installed. Fresh water for the station will be obtained from wells located on the property.

Fuel oil will be delivered by 120,000-bbl tankers through a submerged pipe line extending approximately 3500 ft out into Monterey Bay. A flexible hose at the sea end of this line will be taken aboard the tanker upon arrival and connected to the discharge of its unloading pumps. When not in use, the hose will rest on the bottom of the sea. If conversion to coal operation should become desirable at this station, a spur of the Southern Pacific Railroad will be available for coal deliveries. There is ample space at the plant for the simultaneous storage of fuel oil and coal. Grading at the site was started in September, 1948.

"STATION P," HUNTERS POINT¹

Load growth in San Francisco and on the Peninsula necessitated an increase in power supply for this area. Studies indicated that this could be obtained most economically by installing additional steam capacity at Station P where space was available and a good condenser circulating-water system had already been developed. The original unit at this station was placed in operation in 1929, and is rated 35,000 kw.

The two new 100,000-kw main units and two 7500-kw house units are supplied steam by four new boilers entirely independent of the old unit so far as operation is concerned. Circulating water is drawn from San Francisco Bay. Fuel oil is delivered by barge or tanker to a filling line carried on a pier extending into the bay.

Power generated by the new units is stepped up to 115 kv and transmitted by high-voltage underground cable to the new Mission substation in the heart of the city. Two 115-kv underground cables also connect Station P with Martin substation from where the power may be taken during light load periods over transmission lines to the system outside the city.

The first new unit at Station P was placed in commercial operation on December 12, 1948, and the second followed on January 25, 1949. Construction started in July, 1947, and about 18 months were required to bring the first unit into operation.

¹ "Station P," *Power*, vol. 92, 1948, pp. 586-588.

CONTRA COSTA STEAM STATION

The most concentrated industrial area of the company's system lies in the East Bay region and along the lower Sacramento and San Joaquin Rivers near where they empty into San Francisco Bay. The Contra Costa Station has been located in this area at a point $2\frac{1}{2}$ miles east of Antioch on the San Joaquin River.

The backbone of the electrical transmission system is the 230-kv network running the length of the great Central Valley and carrying power from the many hydroelectric plants in the Sierra Nevada to the principal load centers in the San Francisco Bay area and below. The Contra Costa steam plant was placed astride this network. Its power will be used wherever required in the system, and its location on the San Joaquin River was, among other considerations, decided on the basis of availability of circulating water and proximity to fuel-oil supplies along the upper bay. Circulating water will be drawn from the river which, although subject to tidal action is still essentially fresh. It is believed that stratification and the large volume of water available will reduce the effect of recirculation during unfavorable conditions of tidal and stream flow. Fuel oil will be delivered by barge, tanker, or pipe line. Coal when and if required in the future can be delivered to a spur of the Santa Fe Railroad entering the property.

The initial installation at this plant will include three 100,000-kw main units, three 7500-kw house units and six steam generators. All units are scheduled to be in operation during the first 6 months of 1951. Construction was started in February, 1949.

POWER-PLANT DESIGN AND STATION EQUIPMENT

The steam program outlined in this paper has been and is being planned and co-ordinated by the Pacific Gas and Electric Company's engineering department but, except for the units at Eureka, the plant design and the construction are being carried out by others. Stone and Webster Engineering Corporation has this responsibility for Kern, Station P, and Moss Landing. The Bechtel Corporation has similar responsibilities in connection with the Contra Costa plant.

Structure. In general, each of the four new steam stations is of semioutdoor design, with the turbine room and control bay entirely housed. The boilers are protected by an umbrella-type roof of corrugated transite. The firing aisle is completely enclosed. The buildings are of steel-frame construction with reinforced-concrete walls and roofs. A plan and section of the Contra Costa steam plant are shown in Figs. 6 and 7.

Turbine Generators. Except for the two 1800-rpm Kern units, where delivery was a prime consideration, the remaining eight main turbine generators involved in this postwar program, each with a nominal rating of 100,000 kw, 15 lb hydrogen, are 3600-rpm machines designed for 1300 psig and 950 F. The turbines are of the tandem-compound double-flow condensing type and have four extractions to supply steam to the feedwater evaporators and the closed feedwater heaters. The condensers are single pass with divided water boxes to permit part-load operation on one of the two circulating-water pumps.

The eight accompanying automatic-extraction house turbo-generators are rated 7500 kw and are designed for the same steam conditions as the main units. They operate condensing with a single extraction opening supplying steam for the deaerating feedwater heater. The house units are installed to provide an independent electric power supply for the vital station auxiliaries. They are simple rugged units expressly designed immediately to assume full load in the event of a system disturbance. Normally they will be in operation supplying extraction steam at a constant 5-psig pressure to the deaerating feedwater heaters. System frequency or voltage dips, severe enough adversely to affect station operation, automatically disconnect the main units from the

house bank. Thus, the main units will operate at whatever frequency and voltage the system can develop and will carry essentially full load. Meanwhile the house units furnish normal voltage and frequency to the auxiliaries.

A heat-balance diagram, which is typical of each of the eight main and house units at Station P, Moss Landing, and Contra Costa is given in Fig. 8, for the 100,000-kw load condition.

Steam Generators. All steam generators included in this program are of the radiant type with tangent waterwall tubes in the furnace. Two different methods of superheat control are employed. At Contra Costa and Moss Landing, a portion of the gases are by-passed around the primary superheater, and the position of the by-pass dampers determines the temperature of steam leaving the superheater. At Kern and Station P, the control is by means of a heat exchanger installed in an enlarged lower drum. Part of the steam leaving the primary superheater is passed through this attemperor and is cooled prior to mixing with the remainder. All steam then passes through the secondary superheater and thence to the turbines. Two different types of air heaters are also employed. The first eight boilers in the program are equipped with tubular air heaters, whereas the last twelve use the regenerative type, wherein the heat-exchange elements are exposed alternately to furnace exhaust gases and to incoming air.

The steam generators for Station P and Kern were designed for oil and gas fuels. Conversion to coal, should this become desirable, can be accomplished with some loss in capacity. At Moss Landing and Contra Costa, on the other hand, provision is being made for possible use of coal with full-capacity output. Not only is space being provided for installation of such auxiliary equipment as pulverizers, coal bunkers, and dust eliminators, but the steam generators themselves are provided with larger furnaces to permit burning coal efficiently and without reducing the steaming rate. The difference in furnace size is illustrated by the heat-release rate, which for Kern and Station P is about 30,000 Btu per cu ft-hr on oil at rated load. Heat release for the same conditions at Moss Landing and Contra Costa by contrast is approximately 18,000 Btu per cu ft-hr.

In addition to providing greater volume to permit the slower-burning coal to be consumed before the gases leave the furnace, greater space between tubes in the superheater is provided to minimize effects of slagging of these surfaces. The minimum clear space between tubes in the Kern and Station P superheaters is 1 in. The Moss Landing and Contra Costa superheaters have 2 in. clear. These more conservatively designed boilers are expected to be able to stay on the line longer when burning oil fuel and thereby improve boiler reliability.

Quick Pickup. All of the new steam stations at times will be operated at low loads on stand-by duty and may then be called upon to provide nearly full-load output in a matter of 20 to 30 sec. This quick-response requirement is reflected in the selection of equipment. Boiler feed pumps and draft fans are operated always at full speed immediately ready for full-capacity demand. This is achieved at some loss in cycle efficiency because of the need to resort to dampers, throttling valves and recirculation of boiler-feed-pump flow. The fuel burners and auxiliary equipment have a capacity range of 20 to 1 at Kern and Station P, and 10 to 1 for Moss Landing and Contra Costa. All burners are always in service.

Centralized Control. Centralized control is a basic feature of the general plant layout of each of the stations and the operator at the key point in the control room is in position to maintain visual contact with helpers operating the principal items of equipment. He is able to see the main turbines, house units, and boiler feed pumps on the one hand, and the boiler firing aisle on the other. In addition, he is aided in the operation of the plant by a very spe-

cial annunciator system consisting of banks of large light-type indicators mounted above the various control boards and on the control-room walls between the turbine and boiler rooms. By a combination of horns and signal lights, he is warned of abnormal operating conditions anywhere in the plant. By use of a color code, the relative urgency of corrective measures is emphasized.

At Kern and Station P two main units and their auxiliaries are controlled from one room. At Moss Landing and Contra Costa three main units will be controlled from one room. A block diagram of the Moss Landing Station with identification of the individual control boards is shown in Fig. 9.

Station Auxiliary Power System. The primary auxiliary power system in each of the stations is 4160-volt 3-phase. The switchgear used therewith is metal-enclosed with magnetic-type air breakers. The buses are connected in the form of a ring, one ring bus for each main generating unit. Each bus has connected to it, a house turbine and a house transformer bank. The bus sections are connected together through a bus tie switch, allowing parallel operation if necessary.

The secondary auxiliary-power-system voltage is 480 volt 3-phase, and is a selective radial type consisting of load centers located at strategic locations around the plants. Each load center is equipped with a number of 3-pole electrically operated air breakers of proper interrupting duty. The main load centers are supplied with power from 4160/480-volt stepdown transformers. These main load centers supply power to other load centers scattered around the plant. Each center is sectionalized so that only one half the equipment is lost in case of a bus failure.

Motors of 250 hp and above are connected to the 4160-volt system, while smaller motors are connected to the 480-volt system. In addition, the power for the lighting system is 3-phase, 4-wire, 216/125-volt, supplied by numerous small 3-phase lighting transformers stepping down from 480 volts to 216 volts.

CONCLUSION

The construction program outlined in this paper covers almost 1,000,000 kw of new steam-electric generating capacity which will be added to the area before the end of 1951. This amount of capacity clearly indicates the increased importance of fuel-burning plants to the Pacific Gas and Electric Company. From a system standpoint, the new steam stations not only add generating capacity, but the required interconnecting transmission lines and switching stations will further contribute to system reliability. As integration and growth continues, the need for "quick pickup" steam stations and multiple-boiler per turbine installation probably will tend to decline. The future trends of steam-station design here as well as elsewhere is expected to be in the direction of simplification of equipment and plant layout and still lower station heat rates.

Discussion

M. W. CARTY.⁵ The authors give a clear presentation of the salient factors considered in providing additional electric power supply for the requirements in the great central-valley area of California. The rapid rate of growth in peak demand in that area is probably unprecedented in the United States for any comparably sized territory. It is of interest to note that the economics of the situation for the extensive territory served will lead by 1951 to a 50-50 per cent ratio of steam and hydroelectric power-generating plants. In the power developments recently completed since the end of the war in this area, or now under construction, the added steam capacity will be three times as great as the added hydro power.

⁵ Senior Mechanical Engineer, Stone & Webster Engineering Corporation, Boston, Mass. Mem. ASME.

Fig. 4 of the paper shows clearly the preponderant dependence on hydroelectric power in the northern part of the system and makes evident the strategic value of added steam capacity in the San Francisco Bay area. It is a wise precaution to locate the large steam plants where fuel oil is readily available by tanker delivery as the quantities of fuel are large. The Moss Landing steam plant will produce a net output of 565 kw/hr per bbl of oil when operating under full-load conditions, and approximately 12,800 bbl of oil will be required per day under these conditions. If the plant is operated at the minimum capacity at which the turbines will be capable of quick pickup of load, approximately 1000 bbl of oil will be burned per day without any net output of energy.

The steam plants have multiple boilers per main turbine-generator and this was decided upon, having in mind the requirements of quick pickup of load, the need to remove from time to time metallic adhesions on the furnace tubes resulting from oil burning, and the need to wash off occasionally deposits on the superheater tubes. Satisfactorily large water storage in the boiler steam drums is helpful to give accumulator action at times of quick pickup of load, and multiple boilers are better in this respect than single equivalent large boilers. In a completely integrated and compact system, as distinct from the central-valley area with its long transmission lines, it would be desirable to come closer to the "unit principle" of one boiler per turbine generator without cross-connections, in the interest of lower investment cost and operating simplicity.

The advantages of centralized control are apparent, and this has been a major factor in the general arrangement of the steam plants. The operators have direct vision from the central operating point to the key centers at the turbine generators, boiler feed pumps, and house turbines.

Referring to Fig. 5 of the paper, which shows the Kern steam plant, it is not entirely apparent that the two principal operating levels, main operating floor and ground floor, are each arranged at one continuous uniform level which adds to the convenience of the operators and ease of maintenance activities. This plant is dependent upon cooling towers for cooling the condenser circulating water. For make-up and other requirements at full-load operation, the water requirement is at the rate of 4000 gpm, which is readily obtained from deep wells on the power-plant property.

Fig. 9, the Moss Landing steam plant, shows the boiler-feedwater pumps located on the main operating level, and consequently they are always under the observation of an operator. The house units also are located in readily observable positions and are easily accessible. Fuel oil for this station will come from tankers having a capacity of 120,000 bbl and will be discharged by the tanker pumps operating at 125 psig pressure and will be heated to 140 F, if necessary, in the tanker before delivery. It is expected that the tanker will be able to deliver up to a maximum rate of 8000 bbl of oil per hr through an 18-in. submarine pipe and a 24-in. on-shore pipe, extending to the storage tanks at the steam plant, a distance of approximately 1 3/4 miles.

Arrangements in the steam plants are made with a view to the safety and comfort of the operators, and primarily for reliability of service.

Prevention of trouble from mussel accumulation in the circulating-water lines has received special attention at the Moss Landing steam plant. There are two supply lines to each main condenser, and it is planned to circulate water warmed to 95 F back through one line at a time. The single-pass divided-water-box arrangement of the condenser is well-adapted for this operation. A routine backwash may be established for one condenser circuit per week end, resulting in a normal 3-week time cycle. Perhaps a longer cycle will suffice, and the usual chlorine concen-

tration for reduction of slime formation inside condenser tubes may be increased during the backwashing operation.

C. H. WOOLLEY.⁹ The Pacific Gas & Electric Company is very progressive and has consistently purchased efficient and modern designs of power-generating equipment in order to best serve the rapidly growing population. In 1938 the company with which the writer is affiliated installed the first oil-fired radiant-type boiler for P.G.&E. The single-pass principle of gas flow which results in low fan-power costs and improved operation was incorporated in this design. When these boilers were designed, the serious fouling of superheaters with oil slag had not yet been encountered in California; however, the front row of superheater tubes was staggered to form a 3-row slag screen.

When the next expansion of this company was contemplated

⁹ Proposition Division, Babcock and Wilcox Company, New York, N. Y. Mem. ASME.

in 1941, for Kern steam plant and Hunters Point, the same modern radiant-type boiler was selected, but at that time the oil-slag problem had been encountered, and special provisions were included in the design to reduce the possibility of an outage due to the effect of oil slag. The furnace was changed from the older stud-tube design to touching-tube design, in order to provide a cooler furnace and to eliminate the growth of furnace walls, caused by oil slag penetrating the refractory on the studded tubes, as reported by V. F. Estcourt.¹⁰ The tubes in the first two sections of the superheater were spaced far apart so that oil slag could not close the lanes. The superheater banks were made shallow in order to permit better cleaning by the soot blowers. Provision was made to water-wash the superheater, economizer, and air heater. Drain hoppers were installed under all three of these units of equipment.

Unfortunately, the war delayed the installation of the boilers, and they were not placed in operation until 1948.

When it was necessary to purchase the boilers for Moss Landing and Contra Costa, there was not sufficient operating experience to determine if the same improvements would render the units free from the increasing oil-slag troubles. As the degree of trouble due to this slag had increased throughout the country, it was believed that even greater precautions should be taken to insure continuous operation. The possibility of future coal-firing required that the furnace for the new stations should be larger, and this automatically gave a lower temperature entering the tube bank with oil-firing than would have been used normally for a straight oil-fired job. Fig. 10 of this discussion shows the boilers for the Moss Landing Steam Plant, with which the writer is familiar. The additional precautions against tube fouling were as follows:

The front bank of superheater tubes were placed on 12-in. centers primarily to guard against coal-slag troubles, but automatically, operation became safer for oil-firing. As the gas temperature was reduced and reached the second superheater section the spacing was changed to 6-in. centers which is adequate in this temperature zone to insure against tube-lane pluggage with

FIG. 10 BOILER FOR MOSS LANDING STEAM PLANT

¹⁰ "History and Performance of the Oil-Refinery Steam-Electric Generating Stations of the Pacific Gas and Electric Company," by V. F. Estcourt, published in this issue of the Transactions, pp. 209-222.

either coal or oil slag. Experience has indicated that oil-slag pluggage becomes much less troublesome in the lower-temperature zone existing after passing over two banks of superheater tubes, and it is probable that no pluggage would result if the tube spacing were reduced to 1 in. clear between tubes. However, since fuel-oil slag has become progressively more troublesome, it was decided to make the minimum clearance between tubes in the cooler section of the superheater not less than 2-in. The superheater banks were made extremely shallow so that the soot blowers could penetrate the bank properly. Provision for water-washing the superheater, economizer, and air heater was also incorporated.

The experience of the Pacific Gas and Electric Company in its own plants and the boiler manufacturer's experience in other plants in California, Florida, and elsewhere, were combined in an effort to design and build a boiler unit that would be as reliable as is humanly possible. If the hopes of the designers and operators are realized in these new units, perhaps the availability records will permit the next expansion program to be of the single-boiler single-turbine design, resulting in a further simplified plant design and operation.

ALF HANSEN.¹¹ This paper describes the power system of Northern California, and gives a clear, factual picture of the background and planning of the current expansion program.

Normal rainfall in California varies from $\frac{1}{2}$ in. per year in the desert area in Southern California to 114 in. per year in the northwest area. Water available for hydro-power generation in a dry year is about 40 per cent of a normal year. This can be increased to 60 per cent by the use of storage. Therefore there must be available enough steam-generating capacity to firm up 40 per cent of the hydro capacity.

As the power system grows, available hydro sites become less attractive from a firm power standpoint, a larger percentage of the capacity must be firmed up with steam, and initial cost of development increases. Only about 20-25 per cent of the consumers' dollar pays for the fuel used in a steam-generating plant. Therefore steam generation will assume an increasingly greater share of the power load.

Before the war the power company estimated the division of generating capacity as 60 per cent hydro, 25 per cent steam, and 15 per cent from other sources.

At present (including current expansion) the ratios are 40 per cent hydro, 50 per cent steam, and 10 per cent from other sources.

In the future, best estimates indicate the ratios should be 20-25 per cent hydro, 70 per cent steam, and 5-10 per cent from other sources.

The peak-load curve of the P.G. & E. system from 1914 to date shows the effects of two world wars, drought periods, depressions, and business booms; but if a smooth line is drawn through this curve it indicates an average annual increase of slightly more than 6 per cent. Inspection of the annual peak kilowatt curve in Fig. 2 of the paper shows no increase in 1938, and about 13 per cent in 1947. Therefore there must be enough spare capacity on the system to take care of such unpredictable increases in load as effected by war and business booms.

¹¹ Turbine Engineer and Specialist, Pacific District, General Electric Company, San Francisco, Calif. Mem. ASME.

At the present rate of normal growth, the Northern California power system needs 200,000 kw of additional firm generating capacity every year, a large portion of which will be steam.

Before the war P.G. & E. had about 100,000 kw capacity in old steam units which were shut down and served as "cold stand-by." It is clearly seen from figures given in the paper that these units had to be brought into service, and had to be operated at high load factor during the war. When they are again returned to serve as cold stand-by by the current expansion program, 28 per cent more electrical energy will be produced from the same quantity of fuel. Such improvement in efficiency tends to hold down the cost of electricity in spite of rising prices on equipment and labor. It also helps conserve our resources.

The authors mention that a power-curtailment program became necessary in the spring and early summer of 1948. During the 2-year period 1947-1948, the system-peak demand increased some 400,000 kw over the 1946 peak. Subnormal rainfall during this same period greatly reduced hydro generation and increased irrigation pumping load. During the actual curtailment, the load on the power system was 28 per cent greater than for the same period the preceding year, and in certain irrigation areas 400-1800 per cent greater than during the same period of a normal year.

By close co-operation of the power companies in the West, and pooling of their resources, plus effective use of daylight-saving time, the utility companies were able to pull through without interruption of service and with only a minor rationing program for a short period. This is an achievement of which they may be justly proud.

When the interchange agreement with Southern California Edison Company was terminated in December, 1947, some 70,000 kw of firm power obtained from this source had to be replaced with new steam-generating facilities. However, the first new 75,000-kva unit at Kern near Bakersfield did not go on the line until May 10, 1948, so it was fortunate that the Southern California Edison Company continued to supply power on a nonfirm basis after the expiration date of the firm power agreement.

The paper clearly brings out that irrigation pumping is an ever-increasing portion of the system load. This accounts for the August peak being equal to the December peak in a normal year, and will even exceed it in a dry year. The load factor for the July-August peak is 73-74 per cent, and for the December peak 62-63 per cent.

Centralized control of steam plants has considerable merit from an economic point of view. Reducing the operating force in a steam plant by one man per shift, effects a net annual saving of \$15,000. Such a saving will justify a capital expenditure of about \$120,000 for laborsaving features and devices.

We have stated that the peak-load curve shows an average annual increase of a little more than 6 per cent. Some time in the future the shape of this curve must change, or the power company would have to double its capacity every 12 years. Experts claim there is a definite relationship between the amount of rainfall in a certain area and the number of people that area can support. According to this theory, the saturation point for the State of California is between 23 and 32 million people. Therefore one might venture to guess or predict that the peak-load curve will continue at the present slope for another 12 years.

The Design of Sewaren Generating Station and No. 1 Unit at Essex Station, Public Service Electric and Gas Company

By F. P. FAIRCHILD,¹ NEWARK, N. J.

The author outlines the more important considerations leading to the design of the 100,000-kw unit at Essex and the four-unit Sewaren Generating Station. Outstanding features are semioutdoor boilers at latitude 41°; 1050 F steam temperature; a simplified plant layout, including the unit system; central control; shaft-end house generators; and all-electric auxiliary drive. The improvements in calculated plant heat rates are shown for the progressive steps of the program. Some of the more important electrical and architectural features are described.

THIS paper is concerned primarily with the new Sewaren Generating Station, but inasmuch as the Essex 100,000-kw unit was a definite step in the development of many Sewaren innovations and principles, the two may be considered almost as progressive steps in the same program.

PRELIMINARY STUDIES

The Sewaren site, located on an arm of the ocean between Staten Island and the New Jersey coast in Woodbridge Township, was acquired by the Public Service Electric and Gas Company in 1928. With outlet rights of way it consists of approximately 150 acres, of which 35 acres are used in the present development.

Various studies of the method to be used in developing this site, together with probable capital costs and operating economies, had been made from time to time over a period of years. The essentials of the present layout first were developed in a preliminary way the latter part of 1944, at which time consideration was also being given to the removal of an old 22,500-kw unit at Essex, and the substitution of a 100,000-kw, 3600-rpm, modern unit in its place.

Early in 1945, construction of a simple model of a unit station with semioutdoor boilers was begun. The purpose of this model was to provide better visualization of the unit principle of generating-station design, and looking toward Sewaren in particular, it also incorporated outdoor-boiler-plant design and two-level operation. This preliminary model proved to be of considerable use in discussions with the operating department, executives, and others.

GENERAL DESCRIPTION—ESSEX PROJECT

In March, 1945, the work at Essex Generating Station in Newark, N. J., was authorized. The capacity situation was uncertain at the time, but the installation was justified by economies to be obtained which amounted to an annual saving of about 16 per cent of the estimated cost of the installation. The final completed cost was roughly \$9,300,000.

¹ Chief Engineer, Electric Engineering Department, Public Service Electric and Gas Company. Mem. ASME.

Contributed by the Power Division and presented at the Semi-Annual Meeting, San Francisco, Calif., June 27-30, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-SA-15.

It was decided to go ahead with the Essex installation with one boiler and one turbine, and to adopt all features of a complete unit system, namely, one boiler and one turbine generator with a shaft-end generator to carry all essential auxiliaries, without any cross-connections tying into other units in the station. Central control was also adopted as far as was possible in this installation.

Essex embodied a considerable advance in the design of 3600-rpm turbines and generators. The turbine was the first 3600-rpm machine to use 23-in. buckets. These buckets were put through very thorough tests in a special test wheel before installation on the spindle.

Prior to the Essex installation, the largest 3600-rpm generator in existence was rated 65,000 kw. The Essex main generator was rated 95,000 kw and in addition to being the largest generator at that time, it was also the first to be designed for a hydrogen pressure of 25 psi.

Forced- and induced-draft fans, air preheaters, and flue-dust collectors were placed above the boiler, out of doors. For this outdoor service the manufacturers, in co-operation with Public Service engineers, developed fans with air-cooled bearings, large motors of the totally enclosed fan-cooled type, and air-to-oil coolers for hydraulic couplings, to eliminate water-cooling connections of any kind. In the interest of simplicity and the reduction of make-up, it was decided to omit the usual auxiliary steam header. This departure involved the development of a motor-driven condenser air removal pump, a satisfactory substitute for the usual steam-driven auxiliary oil pump of the turbine, the use of air soot blowing, and the elimination of the reserve steam-driven boiler feed pump. Commercial operation of the Essex unit started in December, 1947.

GENERAL DESCRIPTION—SEWAREN PROJECT

On January 21, 1946, authorization was given for the construction of a generating station at Sewaren, consisting of two 100,000-kw units to operate at 1500 psi and 1050 F. These units were required to meet the system load as forecast for 1948. Substantial operating savings were indicated. These two units started commercial operation at the end of November, 1948. A time-table of important dates concerning these two units appears in Table 1.

A third Sewaren unit was authorized January 9, 1947, because of the rapid growth of load on the system. This unit is scheduled to operate in the fall of 1949. It is a twin of the second unit.

On December 11, 1947, funds were appropriated for the purchase of the fourth turbine generator with step-up transformers at Sewaren, in order to obtain shipment early in 1951. No. 4 is similar to the first three units except that it will be rated at 125,000 kw, and will operate with reheat to 1000 F. Prior to this time a 100,000-kw nominal rated turbine generator was the largest 3600-rpm single-shaft machine available. Studies indicated that the larger equipment can be installed in the space provided for the fourth unit without crowding, and that substantial fuel savings will result from the improved efficiency of the reheat cycle.

Unit No. 1.....	Dec. 1, 1948
Unit No. 2.....	Nov. 30, 1948

The present estimated unit cost of the four-unit station is \$132 per kw for name-plate conditions. This includes all electrical equipment to the high-voltage side of the transformers.

The approach to the basic design of Sewaren was the same as Essex, namely, to develop the unit system to the greatest extent practicable. Here, however, as architectural and structural limitations did not exist, it was possible to accomplish much more in this direction. The Sewaren design makes use of all the features developed for Essex plus two-level operation, semioutdoor boilers, and central control of units in pairs.

SEWAREN PLANT ARRANGEMENT COMPARED TO ESSEX

The Essex unit was installed in the area occupied for 32 years by a 22,500-kw turbine generator and four boilers. Fig. 1 is a view of the Essex turbine room with the new unit in the foreground. No. 2 unit, next to it, is a twin of the original No. 1. The new equipment was arranged to suit the building; whereas at Sewaren, the building was designed to accommodate the equipment. The cross sections of the two plants show this difference. At Essex, Fig. 3, on account of limited floor area,

the fans, air preheaters, flue-dust collector, and stack are above the boiler; coal is brought from the existing bunker by conveyor to a hopper which feeds the pulverizers.

In contrast to this, the Sewaren auxiliary equipment is laid out as near ground level as possible, Fig. 2. The circulating-water pumps are at the screen well; the fans, air preheaters, and dust collectors are out of doors; the stacks are on separate foundations; the pulverizers are placed under the coal bunker. The plant is spread out horizontally.

SEMIOUTDOOR BOILERS

The Sewaren boilers are of the semioutdoor type in which the building encloses the front and one side of each boiler. The exterior of the boilerhouse is shown in Fig. 4. The form of the building in the vicinity of the boilers is shown more clearly in the simplified sketch, Fig. 5. This type of construction saved about \$1,000,000 in first cost of three units. Because of the smaller building volume and reduced heat radiation in the boilerhouse, the building is easier to ventilate and keep clean.

Boiler overhauls will be on an annual basis and will be scheduled for warm weather. By far the greater portion of the boiler-maintenance work is performed inside the boiler furnace, gas passes, and boiler drums. Arrangements have been made to keep the inside of the furnaces and gas passages warm during winter shutdowns, not only for maintenance work but also to prevent freezing of the superheaters.

BOILER DESIGN

The designs of the Essex and Sewaren steam-generating equipment are particularly adapted to each plant layout. At Essex, where the limitation was floor area, the steam generator and its auxiliaries occupy an area of about 70 ft × 60 ft. Coal hopper, pulverizers, coal piping, and burners are fitted compactly under the superheater, economizer, and uptake duct. Coal is brought from the station bunker to the hopper by conveyers.

FIG. 1 TURBINE GENERATOR OF 100,000 KW INSTALLED AT ESSEX IN AREA FORMERLY OCCUPIED BY 22,500-KW TWIN OF ADJACENT UNIT

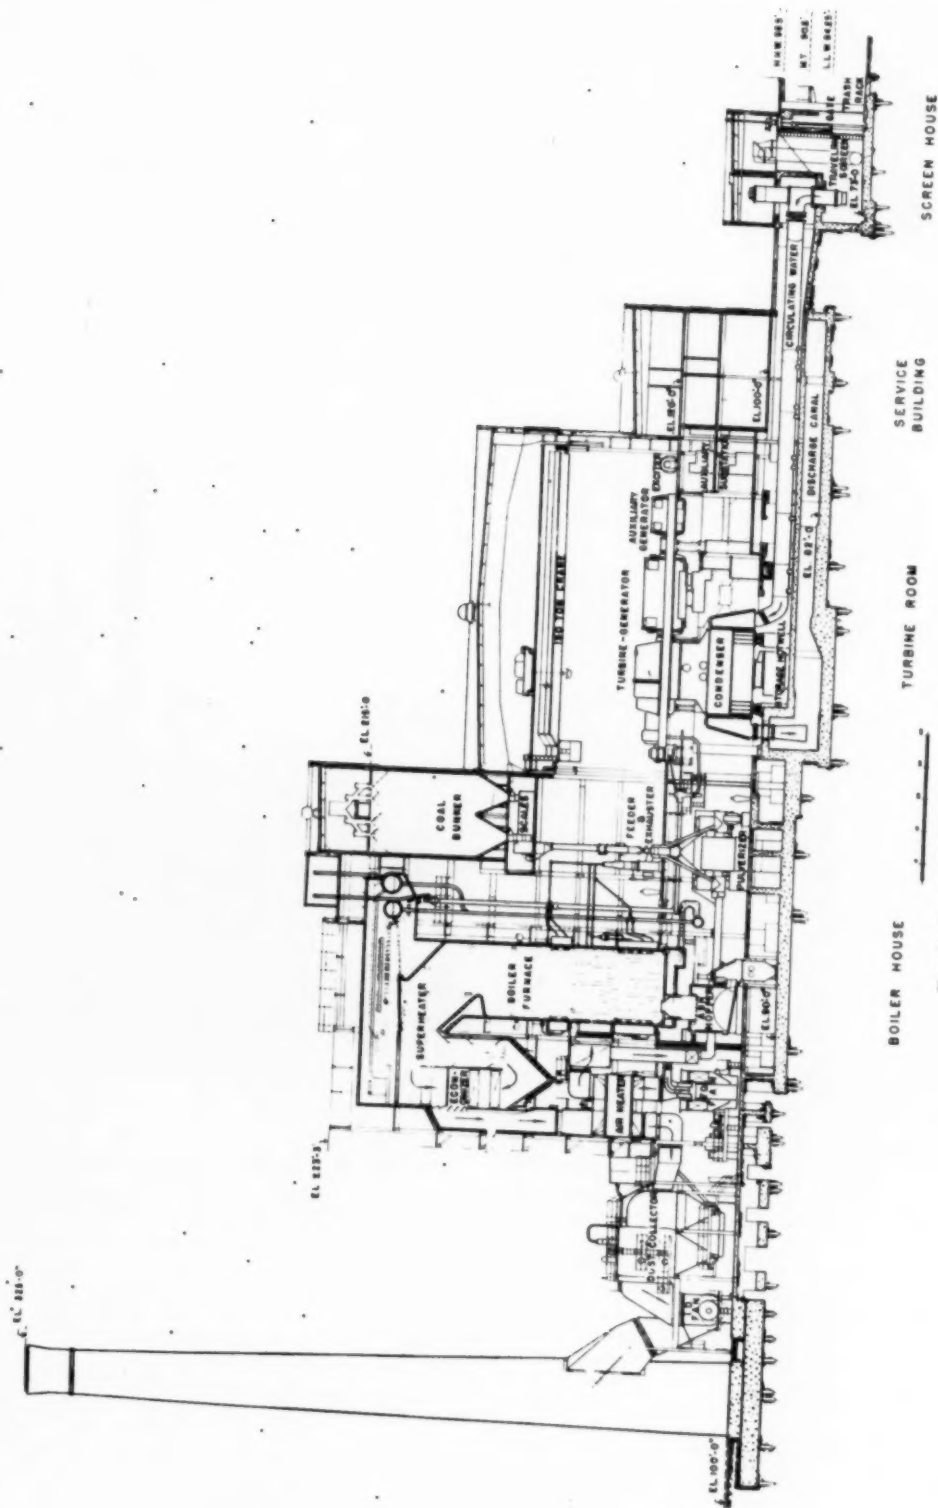

Fig. 2 Plant Cross Section, No. 2 Unit—Sewaren

The Essex boiler, Fig. 6, is a two-drum radiant type, having a continuous rating of 900,000 lb per hr and a maximum rating of 1,000,000 lb per hr for 4 hr with throttle conditions of 1250 psi and 1000 F. The slag-tap furnace, which has a volume of 47,800 cu ft, is divided into two equal volumes by a center waterwall having interconnecting ports in the flame area. Three horizontal ball-type pulverizing mills serve the twelve combination pulverized coal-mechanical atomizing oil burners. Outlet steam temperature is controlled by means of a spray-type attenuator placed between the two sections of the superheater. Auxiliaries include two forced- and two induced-draft fans, two Ljungström air heaters, an economizer, and an electrostatic dust collector.

At Sewaren, where the design objectives included the semi-outdoor feature, two-level operation, and the utmost simplicity, the area occupied by the steam generator and auxiliaries is roughly 160 ft \times 50 ft, about twice the area used at Essex. The drums and superheater outlet header are offset from the furnace so that they are housed in the building. This facilitated the semioutdoor design of the boilerhouse.

Each of the first three Sewaren boilers, Fig. 7, is of the three-drum, radiant type, having a continuous rating of 850,000 lb per hr, and a maximum of 950,000 lb per hr for 4 hr with throttle conditions of 1500 psi and 1050 F. The slag-tap furnace, which has a volume of 52,450 cu ft, is arranged for tangential corner firing at two levels, with combination pulverized-coal and oil burners vertically adjustable to permit positioning of the turbulent burning zone in order to obtain optimum slagging conditions on the walls and floor of the furnace and to effect a certain amount of superheat control. Final steam temperature is controlled by a damper which by-passes part of the furnace gases from the primary superheater to the economizer. As at Essex, there are three pulverizers, two Ljungström air heaters, an economizer, and two forced- and two induced-draft fans. The dust collector is a combination mechanical-electrostatic unit, with the mechanical section ahead of the electrostatic.

FIG. 3 (left) PLANT CROSS SECTION,
No. 1 Unit—Essex

FIG. 4 SEMIOUTDOOR BOILERS—SEWAREN

TURBINE DESIGN AND HEAT RATES

At its best point, the Essex unit has a calculated plant heat rate (based upon turbine guarantees) of 10,400 Btu per net kw-hr. Steam conditions are 1250 psi, 1000 F, and the turbine has a double-flow low-pressure cylinder, Fig. 8. This unit operated 8149 hr of the 8784 hr in 1948 at an average turbine load of about 97,800 kw. The capacity factor was 90.7 per cent. The average heat rate for the year was 10,500 Btu per kw-hr, which is approximately the calculated rate for that load. The average circulating-water temperature was 60.6 F; average back pressure was 1.36 in. Hg. The unit operates regularly at a rating of 110,000 kw.

No. 1 unit at Sewaren is essentially similar to Essex No. 1, except that the steam conditions are increased to 1500 psi and 1050 F. The improvement in heat rate is 4.6 per cent at the best point. This increment includes a one-point improvement

FIG. 5 SKETCH OF EXPOSED PARTS OF BOILERS—SEWAREN

FIG. 6 BOILER CROSS SECTION—ESSEX

in boiler efficiency. The cross section of the turbine is shown in Fig. 9.

No. 2 and 3 units at Sewaren are similar to No. 1 unit except that they have triple-flow low-pressure cylinders. The improvement over No. 1 unit (Sewaren) is 1.4 per cent at the best point. The cross section of the turbine is shown in Fig. 10.

No. 4 unit is similar to No. 2 and 3 at Sewaren except that it is a larger machine, and the steam is reheated to 1000 F. The improvement over No. 2 and 3 units is 4 per cent at the best point, Fig. 11.

The calculated plant heat rates for the units are shown in Fig. 12. The heat-balance diagram for No. 2 and 3 units at Sewaren, Fig. 13, is typical. The system operates without a heater-drain pump. Although the diagram does not show it, the hot-well pump is of the re-entry type. The condensate re-entry is made after passing through the condensate cooler, generator, hydrogen and air coolers, and oil and miscellaneous coolers.

CENTRAL CONTROL

Unit design, with only one boiler per turbine, greatly facilitates central control in a modern electric generating station. For example, the control-panel areas of No. 1 unit at Sewaren compared with the corresponding areas of No. 6 unit at Burlington, a 125,000-kw cross-compound unit with two cross-connected boilers installed in 1943, show some interesting figures. At Sewaren there are 521 sq ft of panel in one location; at Burlington there are 695 sq ft in five separate locations. This concentration of control results in better co-ordinated operation and a reduction in operating attendance.

The arrangement of the control panel at Essex is shown in Fig. 14. Care was taken to make it short so that the operator can see the maximum number of instruments and can reach the greatest number of controls with the least movement. Instruments and controls of lesser importance were placed on the end of the panel wings to make room for the more essential items on the front and center of the panel. While there is no distinct separation between boiler, turbine, and auxiliary boards, the controls are placed on the panels in relative arrangement similar to that of the equipment controlled. The board is arranged so that, in the future, it can be enclosed in a separate room. The plan of the Essex operating floor, Fig. 15, shows the location of the control board. In this installation the generator and electrical auxiliary supply controls were located in an existing electrical control room.

The two Sewaren control rooms are tee-shaped, with the electrical benchboard, Fig. 16, forming the crossbar. The operator sees the two turbine generators through windows just above the benchboard. The other sides of the room, Fig. 17, are occupied by the panels controlling the turbines, boilers, and their auxiliaries. At the rear, there are two windows looking toward the boilers. There are three operators in the control room. Normally, one operates the electrical benchboard of two

units, and each of the other two operates the mechanical equipment of one unit. However, the operators are trained to handle both mechanical and electrical controls, and, at present, each one rotates around the three operating jobs in the control room. The control rooms are air-conditioned and soundproofed. Special attention was given to the lighting, particularly of the vertical panels, for which totally indirect lighting is provided by means of a cove and arched-ceiling design. In the areas between sections of arched ceiling, vinylite eggerate plastic was used to provide a luminous ceiling, which avoids the contrast between lighted and unlighted areas which a solid ceiling would have given. The final design was the result of studies made of a mock-up, erected in the basement of the Public Service Terminal Building in Newark, N. J.

Each control room is situated at the center of the area occupied by the main equipment under its supervision, Figs. 18 and 19.

HIGH-TEMPERATURE PARTS

The steels used in the pressure parts exposed to the highest-temperature steam are listed in Table 2.

NOTE: All compositions given in per cent of alloying materials.

At Sewaren, each unit has two welded joints between the austenitic steel of the stop valves and the ferritic steel of the steam piping. As the stainless steel expands about 50 per cent more than the chrome-moly steel in the range from 70 to 1050 F, there was some concern about the adequacy of a welded joint between the two metals in heavy wall thickness. With the co-operation of the boiler, turbine, and pipe suppliers, a cyclic-heating test was made on several full-size, heavy-wall, welded pipe joints between austenitic and ferritic steels. This test has been des-

FIG. 20 KELCALOY TRANSITION PIECE

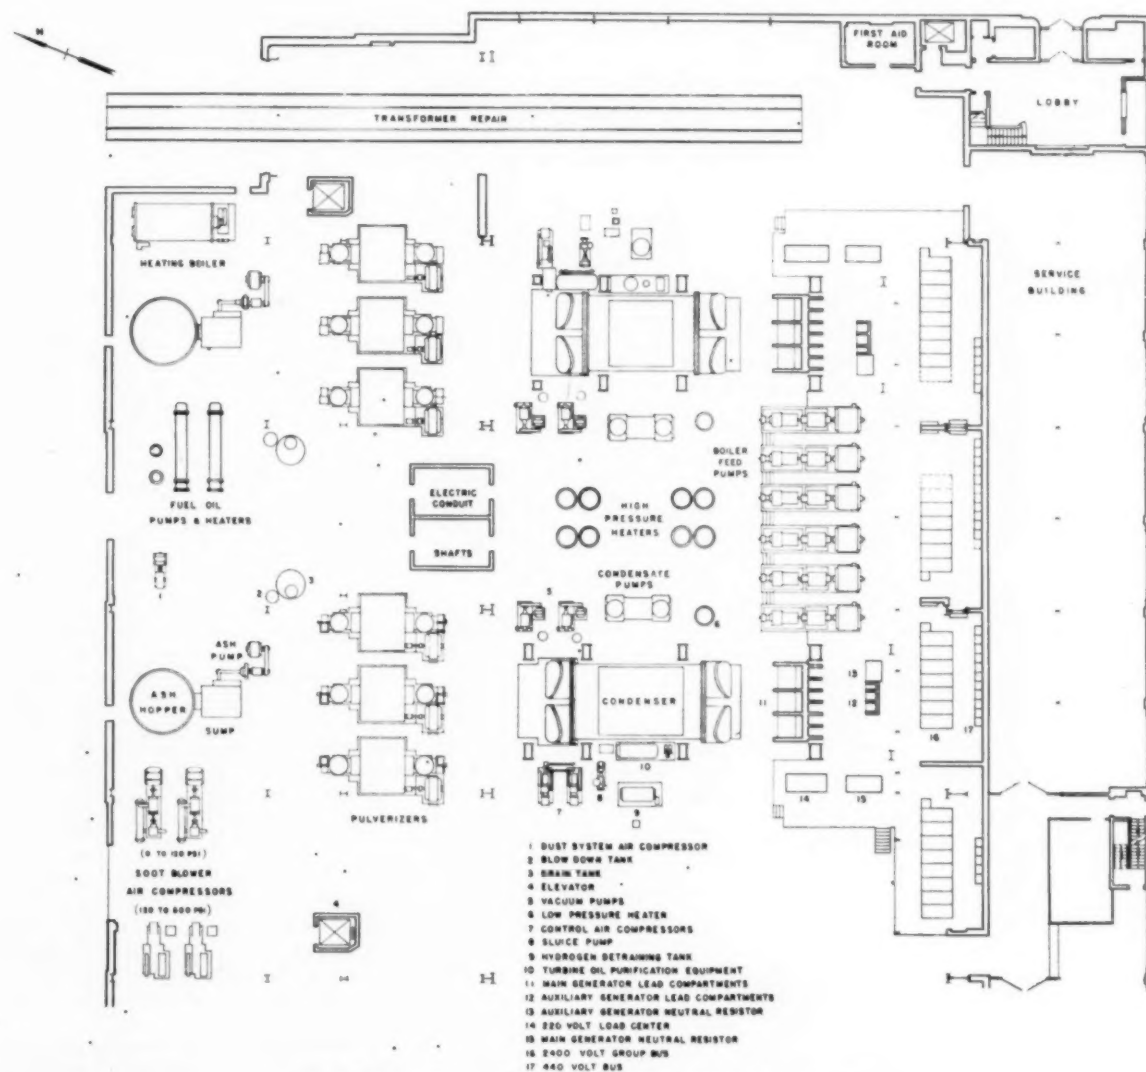

FIG. 21 PLAN OF LOWER OPERATING FLOOR—SEWAREN

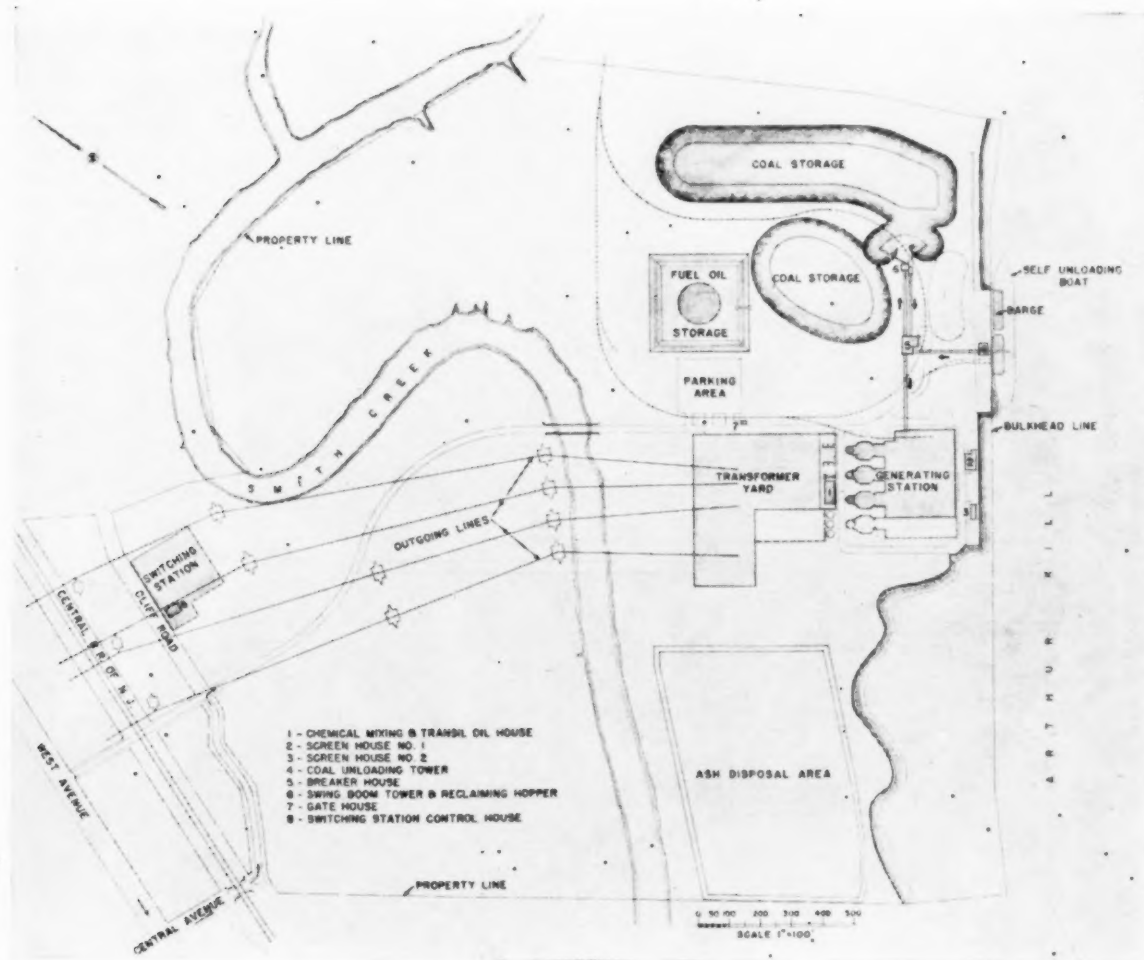

FIG. 22 SEWAREN PROPERTY MAP

cribed fully by H. Weisberg.² The Kelcaloy transition piece finally selected is shown in Fig. 20. The purpose of this arrangement is that the major portion of the interface between the dissimilar metals is longitudinal to the pipe rather than transverse, and therefore is subject principally to shear stress resulting from internal pressure or bending. If failure occurs at the joint between the two metals it should appear as a lap or lamination rather than as a separation straight across the pipe. The transition piece is welded to the stop valves in the shop, leaving a ferritic weld to be made in the field.

The spindles of the stop and control valves of No. 2 and 3 turbines at Seward are cooled with steam from the intermediate header of the superheater. No. 1 turbine valves are not provided with any cooling arrangement.

AUXILIARY POWER

Shaft-end auxiliary generators are used to provide the essential auxiliaries with a direct source of power free from outside dis-

turbances. Normally, each auxiliary generator carries the essential auxiliaries of its own unit. It is rated 7500 kw at 2400 volts, 80 per cent power factor, and is separately excited. The 2400-volt auxiliary buses of each unit can be fed either from the auxiliary generator or from auxiliary transformers connected to an outside source. The two are never paralleled. Relays are installed to throw over automatically from generator to transformer in case of loss of voltage on the generator. Manual throw-over in the other direction is provided for transferring auxiliaries from transformer to auxiliary generator when starting up.

AUXILIARIES

Steam from the high-pressure boilers is used only to run the main turbines. All auxiliaries are electric-motor-driven. At Seward, steam for heating fuel oil, mixing chemicals, and heating the building is supplied normally from the evaporators. There is a heating boiler for use in the event of a complete station shutdown. Every effort has been made to reduce make-up to a minimum.

With the shaft-end auxiliary generator as the source of auxiliary power, the elimination of steam-driven auxiliaries becomes a relatively easier step in station design. One of the problems in

² "Cyclic Heating Test of Main Steam Piping Joints Between Ferritic and Austenitic Steels, Seward Generating Station," by H. Weisberg, Trans. ASME, vol. 71, 1949, pp. 643-664.

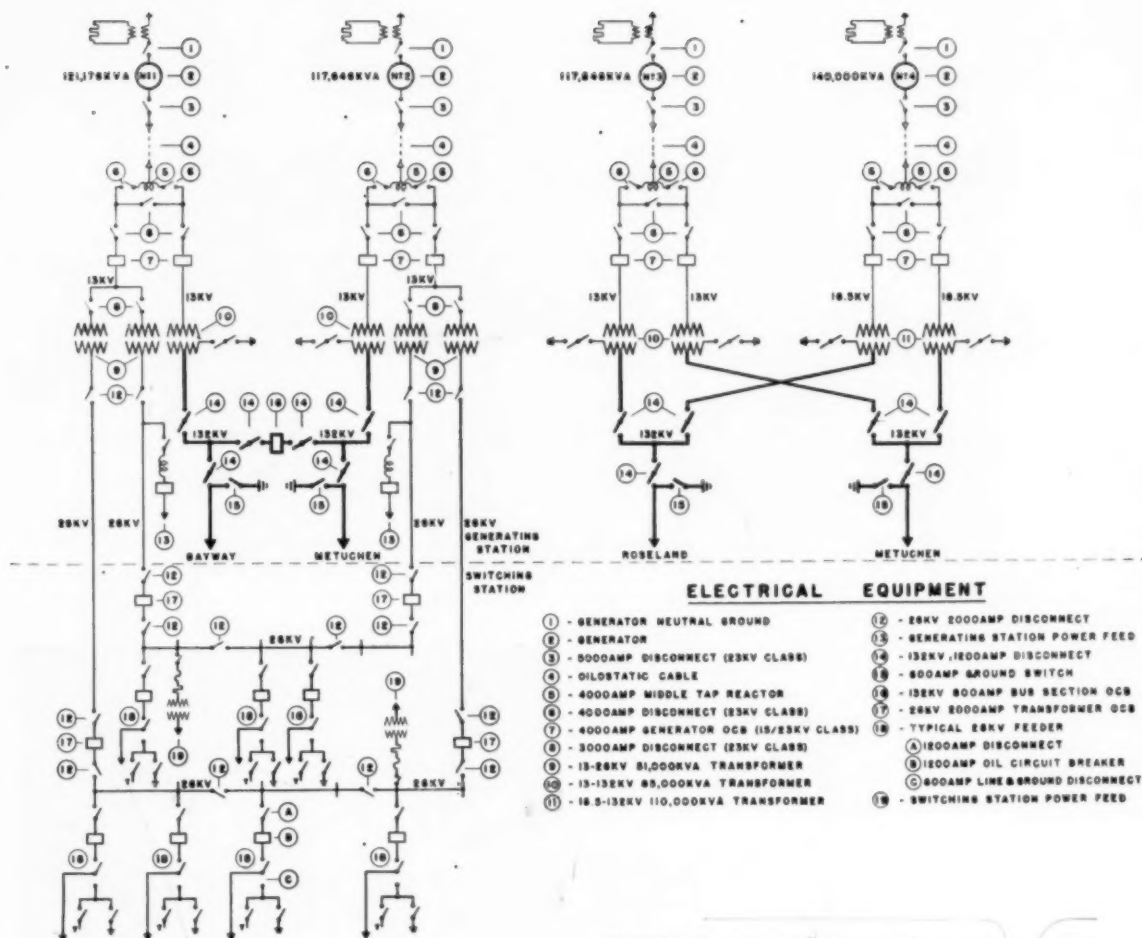

FIG. 23 ULTIMATE CONNECTION DIAGRAM OF THE FOUR SEWAREN GENERATORS

this connection was the substitution of motor-driven, positive-displacement, rotary vacuum pumps for the usual steam-jet ejectors for the removal of noncondensable gases from the condenser.

Before proceeding with this new departure, a Kinney pump of this type was tried out on No. 10 condenser at Marion Generating Station for about 1000 hr. This test revealed that most of the troubles were related to separating the lubricating oil from the water vapor associated with the gases coming from the condenser air coolers. As these difficulties appeared to be surmountable, it was decided to use Kinney pumps at Essex because they offered the following advantages over the steam-jet air pumps: (a) Sufficient capacity at low vacuum to eliminate the need of starting evactors; (b) adaptability to remote push-button starting and stopping; and (c) more complete removal of corrosive gases such as ammonia and carbon dioxide from the system, as there are no inter- and after-condensers (or, alternatively, no wastage of condensate to get rid of these gases).

It was evident after a few months' operation of the Essex pumps that they would do the job and, accordingly, orders were placed for the Sewaren pumps. Operating experience to date has confirmed the expectation of satisfactory operation.

The traditional steam-driven auxiliary oil pump of the turbine

FIG. 24 PLAN OF TRANSFORMER YARD—SEWAREN

FIG. 25 13-KV ALUMINUM BUSES AT SEWAREN

generator was replaced by a full-capacity alternating-current motor-driven pump, backed up by a smaller direct-current motor-driven pump operating from the station battery. This latter pump has sufficient capacity to bring the turbine-generator to a stop if both main and auxiliary pumps should fail.

The arrangement of auxiliaries at the lower operating level of Sewaren is shown in Fig. 21. This plan, which includes only the first two units, is typical for the second pair.

FUEL HANDLING AND STORAGE

Sewaren is designed for normal operation with water-borne fuel. The plan of the property, Fig. 22, shows the coal-unloading tower and breaker house, where the coal is sent either to the bunker or to the swing-boom tower for storage by tractor and carry-all. Both the dock and the unloading tower are designed so that in the future the unloading tower could be mounted on wheels and moved along the dock. Coal arriving by rail or reclaimed from yard storage is dropped into track hoppers feeding a conveyor to the breaker house. A 125,000-bbl fuel-oil tank is located north of the main building.

PRINCIPAL ELECTRICAL FEATURES—SEWAREN

The ultimate connections of the four Sewaren generators to the system are shown in Fig. 23. Each generator feeds into the midpoint of a reactor which takes the outgoing current into two channels. All switching is done between the generator and transformer at 13 kv, except for one 132-kv oil circuit breaker which ties together two lines, closing a transmission loop when the station is shut down. The 26-kv circuits feed the area immediately adjacent to Sewaren, while the 132-kv lines connect to the transmission system for utilization in more remote areas. Fig. 24 shows the arrangement of equipment in the transformer yard.

The 13-kv generator leads extend about 500 ft to the transformer yard in 8-in. oilstatic pipes in tunnels on foundation slabs carrying station power and control cables in one case, and transformer track supports in another case.

Placing the oilstatic cables in tunnels enabled the use of forced cooling, by means of which the copper cross section of the conductors was reduced from 12 to 6 million circular mils per phase, thus effecting a saving in cost and permitting the use of small easily handled cables. Forced air is used to cool the pipes in No.

FIG. 26 ISOLATED PHASE BUS LEADS FROM AUXILIARY GENERATOR—SEWAREN

1 and 3 tunnels. For generator No. 2, the oil is circulated in the oilstatic pipe by a pump and gives up its heat in an oil-water heat exchanger. The forced cooling is required only in hot summer weather. Each generator has twenty-four 750,000-circular-mil oilstatic cables, six in each 8-in. pipe.

The aluminum bus¹ was adopted for the transformer yard after a study showed considerable savings in its installation. Fig. 25 shows portions of the square 13-kv aluminum buses. At the left they are tubular and at the lower right they are formed from two angle sections. A large portion of the savings lies in the use of the

¹ "Welded Aluminum Bus in Outdoor Transformer Yard of Sewaren Generating Station," by D. M. Quick, Edison Electric Institute Bulletin, December, 1948.

FIG. 27 220-VOLTS LOAD CENTER—SEWAREN

FIG. 28 SEWAREN GENERATING STATION

newly developed inert gas-shielded arc system of welding in lieu of the usual bolted connections. This is the first installation ever made using inert gas-shielded-arc welding on outdoor buses of such heavy cross section.

The isolated phase bus leads coming from the auxiliary generator to the 2400-volt service buses are shown in Fig. 26. A stovepipe bus comes from the main disconnecting switch to a potential transformer compartment and to the cross bus. Toward the right it terminates in a rectangular metal-clad enclosure feeding one of the 2400-volt auxiliary buses.

Motors rated at 200 to 2000 hp are supplied at 2400 volts; those between 25 and 200 hp at 440 volts; while those below 25 hp are fed at 220 volts. These latter motors and the station lighting are supplied by air-cooled transformer load center units located throughout the station, Fig. 27.

Totally enclosed motors have been used to the greatest extent practicable. In addition to the fan motors already mentioned,

all motors for the coal-handling system, boiler feed pumps, and the circulating-pump motors of No. 3 and 4 units, are totally enclosed.

BUILDINGS

The architectural treatment of the buildings is simple and functional, with strong horizontal lines resulting from continuous rows of sash and glass block, Fig. 28. At the permanent end of the turbine room there is a visitors' observation balcony which affords an outside view of the easterly end of the property and an inside view of the turbine room. The main entrance and lobby are at the permanent end of the service building. All the window sash are of aluminum, and the principal entrance doors are of stainless steel.

The turbine-room roof is supported by arched girders rather than by the conventional open-truss construction. The temporary end is covered with corrugated asbestos sheets secured to steel

girls. The coal-handling buildings are enclosed with flat transite sheets.

LIGHTING

A high level of illumination is provided throughout the station in the belief that it will yield dividends in better operation, safety, and general housekeeping. In this connection, special attention was given to the turbine room, Fig. 19. Combination incandescent-fluorescent units are mounted flush against the bottom flange of the roof beams to form a continuous fixture containing sixteen 500-watt incandescent lamps with control lenses, and sixty-four 40-watt fluorescent tubes, about 10 kw of lighting load per beam. Relamping and cleaning are accomplished readily from the top of the crane.

SUMMARY

The objectives in the Sewaren design were straightforward simple arrangement which with central control would simplify operation and make for minimum man power per kilowatt; a reasonably efficient cycle that would not be obsolescent at too early a date; and a simple building construction involving a minimum of maintenance throughout its life.

ACKNOWLEDGMENT

The author gratefully acknowledges the assistance of Messrs. E. H. Snyder, H. Weisberg, and P. A. Salmon, all of the Public Service Electric and Gas Company.

Appendix

PRINCIPAL EQUIPMENT FOR NO. 1, 2, AND 3 UNITS AT SEWAREN

Turbine-Generators and Auxiliaries:

1 Turbine-generator (Westinghouse), having nameplate data as follows:

Steam turbine, rated 100,000 kw, maximum 109,500 kw; initial pressure 1500 psi, initial temperature 1050 F, exhaust pressure 1.5 in. Hg, rpm 3600, 32 stages.

Alternating-current generator, rated 121,176 kva, power factor 0.85, hydrogen pressure 30 psi, frequency 60 cycles, phases 3, voltage 13,100 to 14,500, star connected, speed 3600 rpm.

Auxiliary alternating-current generator, rated 9375 kva, power factor 0.80, air cooled, speed 3600 rpm.

2 Turbine-generators (General Electric) each having nameplate data as follows:

Steam turbine, rated 100,000 kw, 23 stages, speed 3600 rpm, maximum capacity 108,500 kw, steam pressure 1500 psig, temperature 1050 F, exhaust pressure 1.5 in. Hg abs.

Alternating-current generator, hydrogen cooled, 2 poles, 60 cycles, 3 phase wye-connected for 13,800 volts; rating at 15 psig hydrogen pressure 111,765 kva at 0.85 power factor, armature 4670 amp, field 1040 amp, exciter 250 volts. Capacity at 25 psig hydrogen 117,647 kva at 0.85 power factor; armature 4920 amp, field 1070 amp.

Auxiliary alternating-current generator, rated 9375 kva, power factor 0.80, air cooled, speed 3600 rpm.

3 Single-pass, divided water box, spring supported, welded steel-shell Foster-Wheeler condensers with storage-type deaerating hot well; one 50,000 and two 60,000 sq ft surface, and 7/8-in.-OD X No. 18 BWG aluminum brass and aluminum bronze tubes.

9 Low-pressure, 2-pass, closed feedwater heaters (Westinghouse), located horizontally in condenser neck.

3 Low-pressure, 4-pass, closed vertical feedwater heaters; and 12 high pressure, 2-pass, closed vertical feedwater heaters (Foster Wheeler Corp.)

3 Condensate coolers, using salt water for cooling (Graham Manufacturing Co.).

Steam-Generating Units and Auxiliaries:

3 Boilers (Combustion Engineering-Superheater, Inc.), each rated 850,000 lb per hr continuous, 1500 psi, 1050 F throttle steam conditions, 52,450 cu ft furnace volume, 15,080 sq ft boiler heating surface; vertically adjustable, tangential firing burners, continuous

slag tap; 2-stage pendant, convection superheaters, 41,800 sq ft heating surface; continuous tube, counterflow, 39,600 sq ft economizer.

6 Ljungstrom regenerative air heaters (Air Preheater Corp.), 104,350 sq ft.

Superheater and economizer refractory walls, sectionally supported (M. W. Detrick Co., George Allen & Son).

3 Ash hoppers, 3 ash pumps and 1 dewatering bin, Allen-Sherman-Hoff Co.

Ductwork, Connery Construction Co.

Boiler and boiler gas-duct insulation, H. W. Porter Co.

Hot air duct insulation, Chas. S. Wood & Co.

Air soot blowers, automatic sequential operation, Diamond Power Specialty Corp.

9 Hardinge pulverizers, 19 tons per hr; 9 raw-coal feeders; and 9 mill exhausters, Foster Wheeler Corp.

6 Variable-speed forced-draft fans, driven through hydraulic couplings, American Blower Corp.

6 Air-cooled radiator for cooling oil of forced-draft-fan hydraulic couplings, Young Radiator Co.

6 Induced-draft fans, 2 driven through hydraulic couplings, 4 louvre controlled, American Blower Corp.

2 Fan-cooled radiators for cooling oil in the induced-draft-fan couplings, General Electric Co.

3 Stacks, double shell, radial brick, 225 ft high, 15 ft diam at top, M. W. Kellogg Co.

Zeolite water softening system, Worthington Pump & Machinery Corp.

3 Evaporators, 30,000 lb per hr each (2 Foster Wheeler Corp.; 1 Griscom-Russell Co.).

3 Evaporator deaerators, Worthington Pump & Machinery Corp.

Coal-Handling Equipment:

Unloading tower and barge puller, McKiernan-Terry Corp.

Bradford breaker, Pennsylvania Crusher Co.

Conveyors, traveling tripper, and swing boom, Robins Conveyors, Division of Hewitt-Robins Inc.

Conveyor belts, Thermoid Rubber Co.

Magnetic separator, Ding's Magnetic Separator Co.

Weightometer, Merrick Scale Manufacturing Co.

12 Automatic coal scales, Richardson Scale Co.

Raw-coal hoppers and stainless-steel chutes, Heilman Boiler Works; Allied Steel Products Corp.

Gates in raw-coal chutes and at bunker outlets, Stock Engineering Co.

2 Tractors, bulldozers and carryalls, Smith Tractor Co.; East-coast Equipment Co.

Dust-Handling Equipment:

Dust collectors, multiclone-Cottrell, Western Precipitation Corp.

Fuller-Kinyon dust-conveying system, Fuller Co.

Redder conveyers between precipitators and dust-pump hopper, Stephens-Adamson Manufacturing Co.

Variable-speed drives, Reeves Pulley Co.

Screw conveyers between economizers and dust-pump hopper, Link Belt Co.

Star feeder valves, precipitator, and economizer hoppers, United Conveyor Corp.

Dust-storage silo, Heilman Boiler Works

Pumps:

6 Vertical, mixed-flow, 47,000-gpm, 345-rpm circulating-water pumps, Foster Wheeler Corp.

6 Rotating-plunger-type, single-stage, vacuum pumps, 550 cfm at 1.5 in. Hg, Kinney Manufacturing Co.

6 Vertical, centrifugal 4-stage, re-entry type condensate and booster pumps; 2090 gpm at 517 ft head, 884 rpm; Worthington Pump & Machinery Corp.

9 Horizontal, centrifugal 8-stage, 1115-gpm at 4,680 ft head, 3465-rpm boiler feed pumps, Worthington Pump & Machinery Corp.

9 Variable-speed hydraulic couplings driving boiler feed pumps, rated 2000 hp at 3550 rpm, American Blower Corp.

4 Vertical, DeLaval, 2500-gpm at 250 ft head, 1760-rpm salt-water service pumps, Turbine Equipment Co.

3 Ash sluice pumps, 2000 gpm at 25 ft head, Worthington Pump & Machinery Corp.

1 Centrifugal fire pump, 1600 gpm, Gould Pumps, Inc.

1 City-water booster pump, 500 gpm, Gould Pumps, Inc.

3 Vertical, DeLaval, rotary-screw, fuel-oil pumps, 140 gpm at 325 psi, Turbine Equipment Co.

2 Pumps for acid-cleaning system, 1000 gpm at 70 ft head, Worthington Pump & Machinery Corp.

9 Sump pumps, Quimby Pump Division, H. K. Porter Co. Inc.

2 Condensate storage tank pumps, Ingersoll-Rand Co.

3 Evaporator feed pumps, Gould Pumps, Inc.

1 High-pressure chemical feed pump, Worthington Pump & Machinery Corp.

4 Continuous chemical feed pumps, Milton Roy, Inc.

2 Condensate return pumps, Worthington Pump & Machinery Corp., and Federal Pump Corp.

1 Circulating pump for oilstatic cable cooling, Sier-Bath Gear & Pump Co., Inc.

1 Laboratory vacuum pump, Schutte & Koerting Co.

2 Fuel-oil-reclaiming pumps, Sier-Bath Gear & Pump Co., Inc.

Air Compressors:

4 Horizontal, single-stage, 150-cfm at 100 psi carbon-ring-control air compressors, Ingersoll-Rand Co.

1 Horizontal, duplex, 2-stage, 660-cfm at 125 psi station-service air compressor, Ingersoll-Rand Co.

2 Rotary, 2-stage, 1035-cfm at 120 psi soot-blower air compressors, Fuller Co.

2 Horizontal, single-stage, 1000-cfm, 120 to 500 psi high-pressure soot-blower air compressors, Ingersoll-Rand Co.

6 Dual-tower silica-gel air dryers for control air, Dehydriair Corp.

1 Air receiver, 1000 cu ft, 500 psi, A. O. Smith Corp.

3 Air receivers, 60 cu ft, 250-320 psi, American Locomotive Co.

Instruments and Controls:

Three-element control of boiler feed pump speed, Bailey Meter Co. Automatic combustion-control equipment, Hagan Corp.

160-point bearing and superheater-tube temperature recorders; and 90-point miscellaneous temperature recorder, Leeds & Northrup Co.

Automatic control of superheater by-pass damper, Leeds & Northrup Co.

Condenser-hot well-level control equipment, Hagan Corp.

Automatic fuel-oil pressure control, Hagan Corp.

Yarway remote boiler-drum-level indicators, Yarnall-Waring Co. Boiler meters, Bailey Meter Co.

Clear and bi-color gage glasses for boiler drums, Diamond Power Specialty Corp.

Miscellaneous gage glasses, Ernst Water Column & Gage Co.

Boiler-draft and pressure gages, Republic Flow Meters Co.

Ashcroft Duragages, Hajoca Corp.

CO₂, pH, temperature, and conductivity recorders, Leeds & Northrup Co.

Industrial thermometers, Taylor Instrument Co.

Piping:

Main steam and high-pressure boiler feed piping, M. W. Kellogg Co.

Intermediate and low-pressure piping, Midwest Piping and Supply Co.; Cornell & Underhill

Circulating-water 48-in. reinforced concrete pipe, Lock Joint Pipe Co.

Strainers, Andale Co.; Leslie Co.

Insulation, Chas. S. Wood & Co.

Valves:

Steel gate and check valves, high pressure, The Lunkenheimer Co. Steel gate and check valves, Wm. Powell Co.; Walworth Co.

Safety valves, Foster Engineering Co.; Manning, Maxwell & Moore Inc.

Bleeder check valves, Schutte & Koerting Co.

Boiler blowdown valves, Yarnall-Waring Co.

Regulating valves, Bailey Meter Co.; Fisher Governor Co.; Swartwout Co.; Schutte & Koerting Co.

Pressure relief valves, Manning, Maxwell & Moore Inc.; Farris Engineering Co.; Foster Engineering Co.; Crosby Steam Gage & Valve Co.

Iron valves, Crane Co.; Chapman Valve Manufacturing Co.; Darling Valve and Manufacturing Co.; Walworth Co.

Butterfly valves for circulating water, Henry Pratt Co.

Electrical Equipment:

9 Reactors, single-phase, mid-tap, 5000 amp, General Electric Co.

4 Transformers, 85,000 kva, 13.2-132 kv, forced oil-forced air, Westinghouse Electric Corp.

4 Transformers, 51,000 kva, 13.2-26.4 kv, forced air, General Electric Co.

4 Station power transformers, 4000 kva, 26.4-2.4 kv, Moloney Electric Co.

2 Station power transformers, 1500 kva, 2400-440 volts, Allis-Chalmers Mfg. Co.

Lightning arresters, 15 kv (6 General Electric Co.; 3 Westinghouse Electric Corp.)

Oil circuit breakers, 15, 34.5, and 132 kv, Westinghouse Electric Corp.

Main generator leads of oilstatic cables, Okonite-Callender Cable Co. Inc.

Auxiliary generator-lead housings, Railway and Industrial Engineering Co.

Disconnecting switches 7.5, 23, 34.5, 132 kv, Railway and Industrial Engineering Co.; Delta Star Electric Co.; Pringle Manufacturing Co.

228 Transformer cooling fans, Diehl Manufacturing Co.

Metal-clad switchgear, 2400 and 440 volts, Westinghouse Electric Corp.

Load centers, 220 volts, Westinghouse Electric Corp.; I-T-E Circuit Breaker Co.

Storage batteries, 125 and 250 volts, Electric Storage Battery Co.

Electric motors, 220, 440, and 2400 volts, 3-phase, 60 cycles, Westinghouse Electric Corp.; Allis-Chalmers Manufacturing Co.; General Electric Co.

Mulsifyre fire-protection equipment, Grinnell Co.

Miscellaneous:

6 Sluice gates, operated by air motors, Coldwell-Wilcox Division, Krajewski Pesant Manufacturing Corp.

1 Traveling water screens, basket type, Link-Belt Co.

1 Traveling water screen with continuous screen cloth, Stephens-Adamson Mfg. Co.

Chlorination equipment, Wallace & Tiernan Products, Inc.

150-ton turbine-room crane, Whiting Corp.

2 Boiler-house elevators, Otis Elevator Co., Westinghouse Electric Corp.

1 Service-building elevator, Otis Elevator Co.

Ventilation and air conditioning, Buensod-Stacey Inc.

Heating boiler, Cleaver-Brooks Co.

Test Department furniture, Laboratory Equipment Co.

DeLaval turbine and transil oil-purifying equipment, Turbine Equipment Co.

Structural steel: Main building, Lehigh Structural Steel Co.; Turbine-generator supports, American Bridge Co.; Coal-handling structures, Morris, Wheeler & Co.

125,000-bbl fuel-oil tank, Bethlehem Steel Co.

Fuel-oil tank heaters, Griscom-Russell Co.

Fuel-oil pressure heaters, American Locomotive Co.

3 Water-storage tanks, 125,000 gal each, Bethlehem Steel Co.

Equipment insulation, Chas. S. Wood & Co.

NOTE: List of principal equipment for No. 1 unit, Essex Generating Station, was published in October, 1948, issue of *Power*.

Designers, Electric Engineering Department, Public Service Electric and Gas Company.

Builders, United Engineers & Constructors Inc.

Architectural consultants, Walker & Poor.

Discussion

C. B. CAMPBELL.⁴ The author has presented a most interesting report on the background experience of his company, culminating now in the modern Sewaren generating station. Certainly this is a plant whose continuing performance will be watched with great interest by all who are concerned with steam-power-generating problems.

The author refers to the installation of new equipment to modernize Essex Station as a definite step in the development of many Sewaren innovations and principles. Actually, it seems, at the expense of greater length and detail, that he could have included the progressive developments previously made by his company in its Burlington, Essex, and Marion generating plants as also having contributed to the latest accomplishment. Taken in their entirety, this whole program presents an excellent chronological picture of the progress in American steam-power-plant practice over the past 15 years.

Table 2 of the paper lists materials used in pressure parts exposed to the highest-temperature steam for the specific units

⁴ Manager of Engineering, Steam Division, Westinghouse Electric Corporation, Philadelphia, Pa. Mem. ASME.

indicated by column headings. It is believed there may be some misunderstanding of these data on the part of those not intimately acquainted with details of design of the equipment. We would like, therefore, to amplify this matter somewhat as regards Sewaren turbine, unit No. 1.

While the main steam-piping system leading to the turbine is of 3 per cent Cr 1 per cent Mo alloy as listed, the inlet steam piping connecting the separately supported turbine control-valve chests to the several first-stage nozzle groups is of 17-20 per cent Cr, 9-13 per cent, Ni, Cb-stabilized steel. Higher alloy was selected for these inlet pipes in order to reduce wall thickness and the length of loop necessary to care for expansion and relative displacement of the terminal connections.

In so far as the turbine is concerned, highest-temperature steam, that is, at 1050 F, is confined only to the throttle valves, control-valve chests, inlet piping, nozzle chambers, and nozzle blocks. Steam does not come into contact with the turbine cylinder proper until heat has been extracted by work performed in the first turbine stage, and its temperature even at maximum loading has decreased to approximately 970 F. It is this reduction from the maximum temperature of the steam supplied which permits the use of $2\frac{1}{4}$ per cent Cr, 1 per cent Mo alloy for the inner turbine cylinder.

The throttle and control-valve bodies and bonnets are of steel forgings of the composition shown in Table 2 under "Turbine Valves." Of the parts enumerated in the preceding paragraph as being subjected to 1050 F steam, castings were used only for the relatively small individual nozzle chambers. These castings are of 16-18 per cent Cr, 11-13 per cent Ni, 1.75-2.75 per cent Mo, with Cb stabilizer.

W. L. CHADWICK.⁵ The author has presented a valuable paper on an outstanding power station, a station which it was the writer's good fortune to inspect early in 1949. The Public Service Electric and Gas Company and its engineers are to be complimented on their courage and foresight in (1) pioneering the use of large units operating on steam at 1050 F, (2) the high efficiencies obtained, (3) building semioutdoor boilers in a comparatively severe climate; and further, for their ingenuity in simplifying plant layouts, centralizing controls, and in eliminating so many of the customary steam auxiliaries. Doubtless many of the new developments which are being field-tested and proved in Essex and Sewaren will soon be accepted standard practices.

The increases in efficiency which the author reports are impressive, the No. 4 unit at Sewaren being expected to gain nearly 10 per cent in efficiency when compared with the Essex unit, which latter unit is an efficient generator by any present standard. This efficiency represents about 665 kwhr per bbl of oil on the Pacific Coast base of 6,250,000 Btu per bbl. Some of the newer stations being built throughout the country are designed for as much as 100 kwhr per bbl less than this 665. The use of eight feedwater heaters in the cycle appears somewhat elaborate, but the efficiency and the station cost seem to justify that use. The use of triple-flow turbine exhausts to offset the higher exhaust losses usually attending 3600-rpm designs is commendable.

The clean simplicity of Sewaren's unit design described by the author not only reduced first cost, but should make for considerably greater operating reliability through elimination of headers and manifolds with their multitude of fittings and valves, each of which is a potential source of an outage. The use of semi-outdoor boilers on the East Coast at a latitude of 41° is an interesting and bold step, but one which seems well-justified by a saving of \$1,000,000 in construction costs of the first three units. The structure arrangement, which encloses the front and one

side of each boiler, is ingeniously planned to give protection to weather-vulnerable equipment at minimum building costs. It is also notable that this efficient station is being built for a total cost of \$132 per name-plate kilowatt.

The advances in simplifying auxiliaries are also significant. The development of air-cooled bearings and fluid couplings, and of totally enclosed motors to facilitate outdoor operation is interesting and creditable. The use of motor-driven vacuum pumps to replace the usual condenser jets puts to test the results of considerable recent discussion and development with several valuable advantages. The air soot blowers and the consequent elimination of many auxiliary steam lines also tests in a major station other recent developments and is a progressive step.

The Sewaren control system is efficient and convenient. The contrast which the author notes between the 521 sq ft of panel at one location at Sewaren and the 695 sq ft of control panel at five separate locations for a comparable unit at the Burlington Station is an interesting indication of the advantages of central control. The Sewaren design, which groups the control of each pair of units into a single control room is practical, convenient, and effective in reducing operating labor.

Electrically, Sewaren is ingeniously fitted to special system requirements.

The use of main turbine-driven house generators for auxiliary power appears to be contrary to the current trend. Most of the newer steam stations supply auxiliaries for each unit as a separate group, as at Sewaren, but use transformer banks, usually directly connected to the generator leads, as auxiliary power sources.

LOUIS ELLIOTT.⁶ To one who knows the author of this paper and holds him in high regard, the description of Sewaren and its basis of design exemplify his tireless application and his high competence. The writer is sure he will take pride, through the years to come, in the great plant to which he has given so much care and work, from the initiation of the project to the completion of construction.

While the design incorporates many modern refinements and new developments, the unit cost reported—\$132 per kw—is moderate.

The writer was interested in the reported reduction in total construction cost, by adoption of semioutdoor steam generators. The saving is given as \$1,000,000 for three units; this is at the rate of roughly \$3 per kw—which happens to be approximately the same unit saving as has been observed in other plants, achieved by similar reduction in structures. It is gratifying to see the adoption of this type of plant construction by a number of utilities operating properties in the East and Middle West, where severe winter conditions are experienced, as well as by companies in the West. The economy achieved is worth while, and the design should not entail serious difficulties in operation and maintenance.

The next step in reduction of structures in steam-plant construction involves use of an outdoor gantry crane, tramping over a low structure housing the turbine generator. This is figured to save around \$3 per kw, additional, in plant cost. The third step calls for the installation outdoors of the turbine and considerable other equipment, with housing limited to that for control room and for protection of certain delicate equipment. The saving as compared with a fully housed plant may be of the magnitude of \$10 or more per kw.

A recent example of the third step in economy is a gas-burning plant just now going into operation in the South, with two 66-mw turbine generators each served by one steam generator. The

⁵ Manager, Engineering Department, Southern California Edison Company, Los Angeles, Calif. Mem. ASME.

⁶ Consulting Mechanical Engineer, Ebasco Services Incorporated, New York, N. Y. Mem. ASME.

executives and engineers on this property are thoroughly in accord with the adoption of the design, and with its substantial savings.

Many of the outdoor plants have been in the South, but a number of stations involving the second step in reduction of structures have been installed and operated in locations experiencing winter conditions.

Plants designed during the past 10 years, incorporating various types of outdoor and semioutdoor construction, have aggregated between 3,000,000 and 4,000,000 kw in capacity. The 150 to 200 plant-years of successful operation of these stations have demonstrated the practicability as well as the economy of that character of design.

C. C. WHELCHER.² The author clearly explains the evolution of the Seward design over a brief but significant period starting with the Essex unit and ending with the reheated Seward unit No. 4. Through all, economic considerations have been a keynote as well as consideration of reliability, always aiming at the designers' goal—the lowest annual cost. This entails not only the most careful consideration of initial capital and operating cost, but also efficiency.

The semioutdoor boiler arrangement has proved to be a natural point of savings here in California and has been used for this reason for many years, but it would seem to present problems, although not insurmountable, where winters are more severe. Serious operating difficulties were encountered this last winter at one of our plants when unprecedented cold weather resulted in the freezing of exposed control and gage lines. This brief contact with the freezing problem has instilled in us considerable respect for the problems which must have been encountered in evolving the semioutdoor design for a colder section of the country. For example, a report has reached us of an experience of a boiler-water level gage freezing on an operating boiler due to a severe building air leakage. We would be interested in a brief résumé of methods used to avoid cold-weather difficulties at Seward.

As pointed out by the author, the centralization of control results in better co-ordination of operations and reduction in operating attendance. It is apparent that this may have been carried to a practical limit. The designer must be aware that as long as equipment is functioning properly few operators are required. The real test of adequacy is during and immediately after disturbances.

The effort expended to minimize required make-up is believed to be well-placed. It is probable that while this will show returns, as far as annual operating costs are concerned, little if any benefit can be derived in the sizing of make-up equipment.

While the omission of the deaerating heater from the Seward cycle may have simplified plant design and operation, and in addition, resulted in a lower initial cost, it would appear that the hazard of feed-pump seizure due to flash may be introduced upon sudden load changes or condensate-pump failures. This problem has been solved satisfactorily in the case of pumps fed from the deaerating heater.

² Chief, Division of Steam Engineering, Pacific Gas and Electric Company, San Francisco, Calif. Mem. ASME.

AUTHOR'S CLOSURE

The author thanks Mr. Campbell for the information clarifying Table 2.

With regard to Mr. Chadwick's comment about main turbine-driven house generators for auxiliary power, the primary objective, as stated in the paper, was to provide the auxiliaries with a direct source of power free from outside disturbances. This is particularly important with pulverized-coal firing where there is danger of the fire being extinguished due to slowing down of the pulverizing equipment with a system voltage drop and relighting when the voltage is restored. We have had a number of trip-outs of high-tension transmission circuits due to dancing conductors caused by ice formation. In some instances these trip-outs have resulted in the separation of parts of the system and the loss of the main generators and their transformer-fed auxiliaries at our older stations. In using a shaft-end auxiliary generator supplying auxiliary buses not tied in with the main system nor the auxiliary system of any other unit, we expect our auxiliaries to operate undisturbed through the most severe disturbances. We realize, of course, that the ultimate in dependability is accomplished by a separate house turbine. The complication involved, however, is too great for the advantages gained. Also, our policy is to drop load rather than allow frequency to diminish.

An important consideration was the size of the turbine-generator unit. At the time that this station was designed, the upper limit of the rating of a single-shaft turbine-generator unit was determined by generator size. Thus the rating of the unit was increased by generating auxiliary power in a separate, shaft-end machine.

In accordance with Mr. Whelcher's suggestion, the following is a brief description of cold-weather precautions for outdoor equipment. The boiler drums, superheater outlet header, gage glasses, and safety valves are placed forward of the boiler and inside the boiler-operating aisle. All stairways serving the outdoor boiler platforms are indoors. Silica-gel driers are used to remove moisture from the compressed air which operates control devices and other similar equipment. Soot-blower mechanisms and other control devices which are vulnerable to icing, are provided with covers or are placed in individual enclosures. Draft fan bearings are cooled by air flow induced by suction from the induced-draft side of the air heaters. Low pour-point lubricating oil of a relatively narrow viscosity range is used in bearings and hydraulic couplings, the same grade being used in winter and summer. Heat generated by slip of the hydraulic couplings of the forced-draft fans is transferred to the air entering the fans by means of radiators mounted at the fan inlets. In the case of the hydraulic couplings of the induced draft fans of No. 1 Unit, radiators with motor-driven fans are used for the same purpose. Air heater bearings are cooled with air supplied by a motor-driven fan.

With reference to Mr. Whelcher's comment about the omission of the deaerating heater, the feed pumps are protected against the hazard of seizure upon sudden load changes by a large storage hot well under the condenser which operates as a surge tank. This hotwell receives water from the head tank via the condenser deaerator when the level falls below a certain point. The system is protected against condensate pump failure by the same head tank which holds a five-minute supply of condensate available to the feedpump suction through a check valve which is held closed by normal pressure from the condensate pump.

Operating Characteristics of the 100,000-Kw Essex Turbine Generator

BY STANFORD NEAL¹ AND VINAL S. RENTON²

On December 18, 1947, the largest 3600-rpm tandem-compound steam-turbine generator ever built up to that time was placed in service at the Essex Generating Station of the Public Service Electric and Gas Company, Newark, N. J. Since it was the first of a new class of turbine for both the manufacturer and the operating company, and since the throttle steam temperature was 1000 F, extensive tests were made to determine practical operation procedures for the new machine. These tests indicate that, even with the high steam conditions of 1250 psig this 1000 F turbine generator can safely withstand starting and loading rates higher than those normally used. The operating instructions for this machine can be revised to take advantage of these characteristics. Additional data are needed for wider application to other machines and designs.

INTRODUCTION

A TURBINE generator must be designed to operate safely and efficiently for many years under conditions of high pressures, high temperatures, and large centrifugal forces. Within 14 ft of the casing length of this particular turbine, the steam pressure changes from 1250 psig to 0.5 psia, and the corresponding temperatures change from 1000 to 80 F. The highest circumferential speed is 1393 fps.

With careful design, a turbine generator can be constructed to operate satisfactorily at a constant load under these severe conditions, but rapidly changing loads or temperatures impose stresses higher than occur at constant load. If all conditions of starting, load change, and steam-temperature change were imposed very slowly, the additional stresses due to changing conditions would be insignificant compared to those of constant load. Since very slow changes are not practical, it is necessary to determine the effects of rapid load and temperature changes, design the machine to withstand them, and then to specify, where possible, safe operating procedures during such changes.

Previous operating experience with turbine generators has shown that, without proper control, the length of starting time and rapid load and temperature changes may cause mechanical damage to the turbine or generator. To illustrate the importance of good operation, several of the extreme cases are mentioned here.

Both the turbine casing and shaft may bow because of non-uniform cooling, after unloading, and the shaft may rub the labyrinth packings during the subsequent start and bow still more. The resulting unbalance can increase to such an extent that vibration may cause damage if the machine is handled improperly. This trouble has been largely prevented in later machines

by rotating the shaft at very low speeds as the machine cools or is heated in preparation for starting.

Since the rate of heat transfer to the various parts is greatly different, crushing of internal fits and surfaces may occur, and the resulting stresses may permanently distort the parts.

When the rotor and stationary parts expand at different rates, mechanical contact may occur and wear the rubbing strips which minimize steam leakage. No serious mechanical damage will result from rubbing strip wear.

An infrequent but unusually severe condition exists during emergencies when water slugs are carried over from the boiler. Thrust-bearing failures and permanent distortions may result.

To reduce the possibility of such troubles, starting and loading rates have, in the past, been determined by experience. The tests described here, and recent tests of other investigators³ indicate that, in some cases, those procedures of starting and loading are unnecessarily conservative, and may even be harmful. An adequate theory of starting and loading effects, substantiated by test data, should permit the establishment of more realistic operating procedures. Such information is important both to designer and operator.

DESCRIPTION OF TURBINE GENERATOR

Since the mechanical description of the machine has been reported separately,⁴ only a few details will be mentioned here. The semisection of the turbine is shown in Fig. 1, and the outline of the turbine and generator in Fig. 2. Figs. 3 and 4 show the inner and outer high-pressure shells. The latter three figures also show the location of several of the instruments used in this investigation.

The tandem-compound machine has a nominal rating of 100,000 kw, and the steam conditions are 1250 psig and 1000 F. The high-pressure section has 19 stages with extraction connections from the 7th, 10th, 13th, 16th, and 19th stages. The double-flow low-pressure section is on the same shaft and has 5 stages with extraction connections from each of the two 20th, 21st, and 22nd stages.

The main generator is rated 111,765 kva at 0.85 power factor with 15 psig hydrogen pressure and 117,647 kva at 0.85 power factor with 25 psig hydrogen pressure. The house or auxiliary generator is air-cooled and rated 7500 kw at 0.80 power factor. Separate motor-driven exciters supply the field electrical requirements.

The turbine and two generators are coupled solidly to one shaft. The unit has an over-all length of 77 ft 7 1/4 in., and weighs 1,120,000 lb.

OBJECTS OF TEST

It was expected that there would result criteria for optimum operation with respect to safety, economy, and flexibility and, further, procedures for operation during emergency conditions.

5 Effect of preheating the generator field before or during

^b The generator preheating tests are expected to be the subject of an AIEE paper by F. W. Gay and H. D. Taylor.

FIG. 6 TEMPERATURE AND EXPANSION DATA FOR (1) A 60-MIN START, FOLLOWED BY LOADING TO 110 MW AT 2.75 MW PER MIN, AND (2) UNLOADING FROM 110 MW TO 25 MW, FOLLOWED BY A THROTTLE-STEAM-TEMPERATURE DROP OF 110 F AT RATE OF 200 F PER HR AND THAT FOLLOWED BY A TURBINE SHUTDOWN

as soon as loading began it increased rapidly to about 975 F, then dropped rapidly to about 900 F, and then increased as the load increased, reaching 975 or 1000 F at about the same time the load reached 110 mw. The throttle-temperature change shown in Fig. 6 is quite typical, except that the initial peak is low. The exhaust-pressure change is quite typical.

Unloading and Stopping. Unloading rates were varied from 0.5 to 3.27 mw per min from loads of 40 or 110 mw. For some tests, the unloading was stopped at 25 mw, and held until steady-state conditions were established. Eight unloading tests were made.

From the typical unloading-test data in Figs. 6 and 7 it can be shown that the turbine cooling rates are low when the throttle steam temperature is held as high as practical.

With normal operating procedure, the stop valve is closed as soon as the load is off and the machine coasts to a stop in

about 20 min. It is immediately put on the turning gear which rotates the shaft at about 3 rpm to prevent bowing because of nonuniform cooling. The stopping cycle introduces no trouble and no tests were planned or made.

Throttle Steam Temperature Change. The throttle steam temperature was changed to 100 F at rates of 50 F and 300 F per hr at a load of 110 mw and at 200 F per hr at a load of 25 mw. Five tests of this type were made. Typical tests are shown in Figs. 6 and 7.

Load Dump and Fast Pickup of Load. The load was dumped by opening the main- and auxiliary-generator circuit breakers. After a no-load period of from 3 to 15 min, loads of over 110 mw were picked up in times of 13 to 19 min. For one test, the auxiliary-generator circuit breaker was not opened. Three tests were made and are shown in Fig. 7.

FIG. 7 TEMPERATURE AND EXPANSION DATA FOR (1) THREE LOAD DUMPS FROM ABOUT 110 MW, FOLLOWED BY RAPID PICK-UP OF LOAD, AND UNLOADING FROM 110 MW TO SHUTDOWN AT 0.45 MW PER MIN, AND (2) THROTTLE-STEAM-TEMPERATURE CHANGE OF 100 F AT RATE OF 300 F PER HR AT A LOAD OF 110 MW

As a matter of interest, the maximum speed reached by the turbine was 106.1 per cent of normal. A calculated time of only 0.85 sec is required for the turbine generator to reach 110 per cent speed after the circuit breakers are opened with full-load steam flow going through the turbine.

TEST RESULTS AND DISCUSSION

It would have been desirable to show more of the original data, but their volume made necessary the presentation of these few summarizing curve sheets. As an example of the amount of data obtained, a typical start and load cycle required about 7000 separate observations of temperatures, pressures, and loads, together with the continuous records of load, four expansions, and throttle, crossover, and exhaust temperatures and pressures.

Heating of Turbine. A description of the temperatures during a start is of great assistance in understanding the heating which occurs. Although the internal steam temperatures were not measured, these test data and previous experience indicate that the values quoted are of the right order of magnitude.

With the initial steam temperature at about 750 F during a start, and a calculated temperature drop of about 150 F in the first stage, steam will be supplied to the following turbine stages at a temperature of about 600 F. Steam of this temperature also leaks through the first section of the high-pressure packing and then divides to flow through the remaining sections of the high-pressure packing and between the inner and outer shells into the tenth stage or out to the tenth-stage feedwater heater.

Then, during a start, the valve chest and first-stage nozzle box should approach 750 F, and the remainder of the forward end of the outer and inner shells should approach a temperature of about 550 F. At the tenth stage the steam temperature will drop by perhaps 200 F, so that that section of the inner shell should approach an intermediate temperature between the inner steam of about 400 F and the outer steam of about 600 F. The last 9 stages of the high-pressure turbine will approach temperatures averaging about 350 F. Although the high-pressure turbine tends to equalize in temperature during cooling, the data show that the low-pressure end is usually about 100 F cooler than the high-pressure end. This distribution tends to match metal and steam temperatures. The first stages of the low-pressure turbine should approach a temperature of about 250 F, and the last stages should have temperatures ranging from 100 F to 250 F, depending upon the length of the start.

If the initial temperatures of the high-pressure turbine are approximately 450 F, there should be little change in turbine temperature during a start except in the valve chest and nozzle box. The initial temperature of the low-pressure turbine also should be little changed. Very short starts should then be possible, since the turbine and steam are near the same temperatures. The test data indicate that a starting time of 20 min is satisfactory for this condition.

If the initial temperatures of the high-pressure turbine are approximately 150 F, the start should be somewhat slower, since the turbine is cooler than the steam and heating will take place during the start. The longer start will permit the turbine to approach the 450 F equilibrium temperature for 750 F throttle steam. The test data indicate that a starting time of 50 min is satisfactory for this condition.

If the initial temperature of the high-pressure turbine is 750 F, the turbine should be started with 850 or 900 F steam to prevent cooling toward the 450 F equilibrium temperature which occurs with 750 F throttle steam. If the boiler cannot supply such high-temperature steam at the start, the starting time should be very short, followed by rapid loading to 30 or 40 mw. A starting time

of 10 min is suggested for this machine under these conditions.

With the turbine at initial temperatures of about 450 F, some starts show very rapid temperature drops of 50 or 100 F at the steam chest and in sections of the outer shell near the inlet steam pipes. It is believed that more careful heating of the steam pipes and stop valve might prevent this cooling and so keep the subsequent heating gradients at a lower value. Further testing is necessary to establish the proper techniques. A similar effect occurs when the turbine is started with steam colder than the machine and this, likewise, should be avoided.

Typical heating curves at several places in the turbine casing are shown in Figs. 6 and 7. An examination of the rate of heating will give a measure of the stresses caused by the transient. With initial temperatures of the high-pressure turbine of approximately 400 F and, during starts of 20 to 60 min, only the steam chest and two other temperatures on the inner shell show any appreciable change. All other temperatures rise only after loading starts. Fig. 8 shows the maximum rate of heating as a function of the rate of load increase. Not only does the maximum rate of heating vary at different places, but it occurs at different

FIG. 8 MAXIMUM RATE OF TEMPERATURE CHANGE AT REPRESENTATIVE LOCATIONS DURING STARTING AND LOADING PERIOD

times during the heating cycle. The steam chest shows its highest rate when loading starts and as steam temperature rises very rapidly by about 200 F. The lowest value of the maximum gradient in the high-pressure turbine occurs in the outer-shell flange 10 to 30 min after a load of 110 mw is reached. As an example of heating rates at a particular time, Fig. 9 shows the rates at a load of 50 mw during loading to 110 mw.

With the initial temperatures of the high-pressure turbine at approximately 150 F, considerable heating takes place before loading. However, the maximum rates are not reached until after the loading starts. The preliminary heating is of such an amount that the subsequent maximum gradients are not greatly different from those that occur when a start is made from an initial turbine temperature of 450 F.

The heating data in Figs. 6 and 8 show that some of the temperature gradients in the turbine are very nearly the same as the temperature gradient of the steam. If the rate of increase of steam temperature were constant during the loading period, the maximum heating gradients in the shell could be reduced to about a quarter or third of the test values.

FIG. 9 RATE OF TEMPERATURE CHANGE AT REPRESENTATIVE LOCATIONS AT 50 MW DURING LOADING FROM ZERO TO 110 MW

A study of the calculated heat-transfer coefficients shows that the rate of turbine heating as the load is increased should not be greatly different from the rate of cooling as the load is decreased for the same change of load and the same rate of load change. The order of difference is probably about 30 per cent for the range of $1/2$ to full load. This occurs since, over that load-range, the range of temperatures caused by the load change is relatively small. However, when the turbine is started and loaded from room temperature, the temperature differences become relatively large. In stages which change from dry to wet as the load changes, the rate of cooling will be somewhat higher and the general relation given in the foregoing will not apply.

Longitudinal and Circumferential Temperature Distribution. The relation between steam and shell temperatures is shown in Figs. 10 and 11, for loads of 35 and 117 Mw. Of particular interest is the effect of discharging the steam from the first section of the high-pressure packing through the outer shell at the tenth stage. This tends to keep that portion of the outer shell much hotter than the tenth-stage steam. The flanges on both inner and outer shells remain appreciably colder than the corresponding cylindrical sections of the shells. A large section of the inner shell is colder than the outer shell at the light loads. These effects can be explained as a rather complicated combination of the radiation from the steam chest, heat transfer from the packing and valve steam leakage, and heat conduction through the inner shell.

The circumferential temperature distribution was measured at several sections of the outer shell. At constant load, the largest difference around the shell was about 50 F. Differences of about 125 F were observed during both loading and cooling cycles. Previous experience indicated that the differences during cooling would be much greater if the turning gear were not used.

At one shutdown, the exhaust-hood manholes were opened shortly after the machine was shut down and with the turbine still on the turning gear. The ventilation with room air cooled the machine very rapidly. Temperature differences of about 300 F were observed between top and bottom of the outer shell. Certain turbine parts cooled 500 F in 20 min with the major part of the temperature drop at the rate of 3000 F per hr. Such rates are considered to be undesirably high.

Shell and Differential Expansion. Shell expansion is a measure of the average temperature of the shell and, during temperature changes, shows the speed with which the average shell temperature approaches the steady-state value. Differential expansions are important since they indicate the relative movement of the rotor and shell and show when rubbing can occur.

The magnitude of the expansions for steady-state conditions is shown in Fig. 5. (For a more specific description of how these expansions were measured, see the Appendix.) For transient conditions, the greatest change from the initial, steady-state values during load and temperature variations, is shown in Fig. 12. With loading rates higher than 1.0 mw per min, the maximum change for the No. 1 differential expansion is practically constant for either loading or unloading and is well below the value, which would cause rubbing. No. 2 and No. 3 reach maximum values of the greatest change and then decrease as loading rate is further increased. Since the clearances in the low-pressure turbine are relatively large, the higher maximum differences cause no concern.

Such deviations of differential expansion are functions not only of loading rate but also of the size of the load change and of the initial temperature of the turbine (or the initial load). The maximum change of the No. 1 differential expansion is plotted in Fig. 13 as a function of loading rate. The dotted and solid lines show the effects of load ranges of 0 to 40 and 0 to 110 mw, respectively. The effect of initial turbine temperature is large and shows why loading rates must be adjusted for this factor.

With the longitudinal variations of shell and steam temperature such as are shown in Figs. 10 and 11, the shell and differential expansions can be calculated for the steady-state conditions and show reasonable checks with the measured values. For this purpose the turbine-rotor temperatures were estimated from the steam and bearing-oil temperatures.

An exact calculation of the differential expansion during transients is difficult because of the irregular shapes, the wide variation of steam velocities and heat-transfer coefficients, and the indeterminate heat-transfer characteristics of metal joints of various types. From the measured differential expansions, estimates of the over-all heating rates of both the rotor and shell can be made. With these rates and the calculated steady-state expansions, maximum values of the differentials during transients can be predicted for any turbine of this type. The rates and predicted expansions check well with previous experience.

Change of Throttle Steam Temperature. A change of throttle steam temperature causes a change of turbine temperatures and expansions. In some load ranges, these changes are much like the effect of a load change at constant throttle temperature.

Since this machine has stage valves which by-pass the second and third stages starting at loads of about 93 mw, the change in temperatures and expansions is small for the load range from 93 to 117 Mw. However, between loads of 37 and 93 Mw, a load change of 33 Mw at constant throttle temperature is somewhat the equivalent of a throttle temperature change of 100 F at constant load. It follows that a load change at the rate of 1.65 Mw per min is similarly the equivalent of a throttle-temperature change at the rate of 300 F per hr under the conditions just given.

The data show that the differential expansions for a load change from 0 to 40 Mw are about the same as those for a throttle-steam-temperature change of 100 F.

This concept of similarity is useful in analyzing and applying the test results, although it should be noted especially that local effects, such as heating of the steam chest and the first-stage nozzle, are very different for the two types of change.

Exhaust-Steam Temperature. During a start, the maximum temperature of the steam in the exhaust hood occurred just be-

FIG. 10 LONGITUDINAL TEMPERATURE DISTRIBUTION AT CONSTANT LOAD OF 35 MW
(Steam temperatures from heat-rate test.⁷)

FIG. 11 LONGITUDINAL TEMPERATURE DISTRIBUTION AT CONSTANT LOAD OF 117 MW
(Steam temperatures from heat-rate test.⁷)

FIG. 12 MAXIMUM CHANGE OF DIFFERENTIAL EXPANSION (Solid lines show maximum change occurring during starting and loading, with initial turbine temperature approximately 450 F, and during unloading from full load to 25 mw. Dotted lines show maximum change during 100 F throttle temperature change at constant load.)

FIG. 13 MAXIMUM CHANGE OF DIFFERENTIAL EXPANSION FOR HIGH-PRESSURE TURBINE ONLY (Initial turbine temperature is shown as parameter. Solid lines show load changes from zero to 110 mw. Dotted lines show load changes from zero to 40 mw.)

fore the machine was loaded. The exhaust-steam temperature rises because of the large rotation losses in the last stages. Since those losses are proportional to exhaust pressure, and since that pressure was changing rapidly and was not the same for all tests, the data show some scatter. However, in general, the longer the starting time, the higher the maximum exhaust-steam temperature. The maximum temperature observed during a start was 230 F, which is well below the recommended maximum of 250 F.

At times it is necessary to operate a turbine generator at synchronous speed at no load. Although no tests of this nature were planned, operation for 30 min resulted in a temperature of 225 F. The exhaust pressure at that time was about 1.5 in. Hg. Steady-state conditions had not been reached, and the temperature would have risen further had the test been continued.

Steam-Chest Temperature. The largest observed difference between the throttle steam temperature and the outer surface of the steam chest was 300 F during a starting and loading period. Because of the high temperature drop from steam to

metal, the maximum temporary temperature gradient in the metal, calculated from the test data, was 270 F per in. which occurred when loading at 2.75 mw per min.

At steady loads, the gradient would be about 18 F per in., and the stress due to temperature would correspond to about 4500 psi in tension on the outer fibers and about the same amount in compression on the inner fibers. The calculated heat-transfer coefficient on the inside of the steam chest varied from about 3 to 350 Btu/(sq ft) (hr deg F) as the load changed from zero to maximum.

Inner-Shell Temperature. The temperatures of the inner and outer surfaces of the inner shell were measured at two places near the discharge of the first stage. At high loads, the temperature of the inner surface was hotter than the outer, although the steam flowing over each surface was supposed to be at the same temperature. The difference is largely due to the high heat gain on the inside, the high steam velocity, and the large heat loss by radiation from the outer surface. The magnitude of the difference varied from 75 F at constant load to 115 F during loading, and 70 F in the opposite direction during unloading, Fig. 14. The maximum temperature gradient in the inner fibers, as calculated from test data, was 54 F per in., and occurred during loading at the rate of 2.75 mw per min. This is only about twice the average gradient at constant load.

The 75 F temperature difference would cause a stress of about 7300 psi in the cylindrical part of the shell and should cause little concern. The maximum temperature gradient at the inner fibers of the inner shell will cause stresses of about 10,500 psi.

FIG. 14 MAXIMUM TEMPERATURE DIFFERENCE FROM INNER TO OUTER SURFACE OF INNER SHELL OF HIGH-PRESSURE TURBINE AT FIRST STAGE

(Solid lines show effect of starting and loading, and of unloading cycles. Dotted lines show effect of temperature changes at constant load. During unloading, direction of temperature difference reverses. Both positive, steady-state, and negative maxima are shown.)

Flange and Bolt Temperature. The greatest temperature difference between a bolt and its adjacent flange under steady-state conditions was about 30 F and was about the same for inner-shell studs and outer-shell bolts. During load and temperature changes, the maximum temperature difference between an outer-shell bolt and the adjacent flange was never more than 60 F, Fig. 15(D), for a loading cycle and was smaller for an unloading cycle. The bolt was hotter than the flange, and this indication, to a large degree, may be because the thermocouple inside the flange was not at the bolt center line, Fig. 18(E). Also the radiation from the hot side of the bolthole tends to heat

FIG. 15 MAXIMUM TEMPERATURE DIFFERENCES DURING LOAD CHANGES AT REPRESENTATIVE LOCATIONS IN TURBINE (Starting and loading data based on initial turbine temperature of about 450 F.)

the bolt faster than the flange, since the small space between bolts greatly restricts the flow of heat to the outside. It should be noted that the temperature of bolt and flange were measured only at one point.

The stress change with a bolt 60 F hotter than the flange would be about 12,000 psi with an incompressible flange and would relieve the initial tension on the bolt. Since the flange is compressed, the difference in stress may be reduced to about 9000 psi.

The temporary temperature differences between the hottest inner-shell bolt and adjacent flange were as large as +125 F and -75 F, Fig. 15E, during a loading period, and the direction of the difference changed with loading rate. The change is believed to be due to the relative amount of heat flow from the interior of the inner shell to the bolt.

Flange and Thin Section of Shell. The largest temperature differences observed in adjacent stressed parts were between the outside of the thin cylindrical section of the shell and the interior of the thick flange directly under the steam pipe (OU3R-OF11) and occurred during loading. These differences are shown in Fig. 15(A) as a function of loading and unloading rates.

As with the expansions, the important variables which affect this temperature difference are (1) rate of load or throttle-temperature change; (2) magnitude of the change; and (3) initial turbine temperature. Fig. 16 shows the test points with the curves extrapolated to 5 mw per min loading rate for several initial temperatures of the turbine. The extrapolation is believed to be accurate to about 75 F.

If this temperature difference is considered to be a measure of stresses, very interesting inferences can be made from the relation of that difference to loading and unloading rates. If repeated starts with loading at the rate of 1 mw per min can be made safely from an initial temperature of 150 F, with resulting temperature differences of 450 F (from Fig. 16), then loading at the rate of 5 mw per min will result in temperature differences of 530 F, or only 80 F more. Following the same argument, with initial turbine temperatures of 400 F or higher, loading

FIG. 16 MAXIMUM CHANGE OF TEMPERATURE FROM THIN CYLINDRICAL SECTION OF OUTER SHELL TO INTERIOR OF ADJACENT FLANGE (Initial turbine temperature is shown as parameter. Solid lines are for load change from zero to 110 Mw. Dotted lines are for load change from zero to 40 Mw.)

rates of greater than 5 mw per min can be made with no greater probability of trouble than for the start from 150 F and loading rate of 1 mw per min.

The temperature differences for load ranges of zero to 40 mw and of zero to 110 mw are shown by the dotted and solid curves in Fig. 16, with initial turbine temperature as the parameter. Initial turbine temperature appears to have a more important effect than the amount of loading when it is considered that the usual steady-state throttle-steam temperature is 80 F lower at a load of 40 mw than 110 mw. This is approximately the difference in temperature between the two sets of curves.

The highest calculated average heat-transfer coefficients on the interior of the outer shell are 3.2 and 11.9 Btu/(sq ft) (hr deg F) for convection and radiation, respectively. The low value of the convection coefficient is due to the low velocity of the steam flowing between the two shells.

The maximum temperature gradient on the inner surface, as calculated from the test data, was about 27 F per in., and was the same at the flange as at the thin section. This would correspond to the negligible stress of about 2000 psi. This stress affects only the inner fibers and is reduced progressively with distance from the inner surface. Other stresses, such as are caused by the difference between the temperature of the thin section of the shell and the adjacent flange, tend to distort the shell. The magnitude of these stresses and the amount of distortion depend upon the configuration and size of the shell and are difficult to analyze.

At steady state, the calculated average temperature gradient is about 5 F per in. in the thin section of the shell and about 3.5 F per in. through the flange. Fig. 17 shows the calculated and measured temperature change of a thin section of the shell and of the flange at the hot end of the outer shell as a function of time after start of loading. The agreement is good and represents a sample of the analysis now progressing.

Other Aspects of Test Results. The limitations of the tests must be realized. No temperatures were measured on the nozzle partitions, diaphragms, or rotor. The bucket and partition edges will heat rapidly because of the small mass and the high heat transfer and may cause permanent and undesirable distortions. The calculated heat-transfer coefficient of the first-stage nozzle partition is about 1000 Btu/(sq ft) (hr deg F).

It is known that the diaphragms will distort when heated or cooled rapidly. However, during the tests there was no evidence that the distortion was sufficient to cause the diaphragm packings to rub the shaft.

Temperature stresses in the shaft and wheels must be con-

FIG. 17 MEASURED AND CALCULATED TEMPERATURE IN THIN SECTION OF OUTER SHELL AND INTERIOR OF ADJACENT FLANGE WITH LOAD CHANGE FROM ZERO TO 110 MW AT RATE OF 2.75 MW PER MIN (Initial temperature of turbine at start about 400 F.)

sidered, and it is hoped that techniques will be developed for measuring temperatures of the rotating parts. Such data will complement the theoretical work which is now proceeding.

Some effects of rapid changes of load or temperature may result in small permanent distortions which may be cumulative and which may be measurable only after many cycles.

FUTURE TEST PROGRAM

Analysis of these data is continuing and, after further study, it is expected that additional tests will be made at higher rates of load change and several initial turbine temperatures.

A similar 100,000-kw turbine generator but with steam conditions of 1500 psig and 1050 F, and a triple-flow low-pressure section has recently been installed in the Seward Generating Station of the Public Service Electric and Gas Company. The machine has been instrumented similarly since more severe steam conditions made temperature and expansion data even more desirable. Although the initial steam temperature is 50 F higher, preliminary data indicate that the outer shell is about 150 F cooler than that of the Essex turbine. This desirable end has been accomplished by an ingenious cooling scheme. It is expected that complete results will be reported later.

CONCLUSIONS

Although the analysis is not complete, the following procedures are justified by the test data and are consistent with previous experience. They are recommended specifically for the Unit No. 1 Essex turbine generator.

1 In an emergency, a load of any size can be dropped instantly and, after no-load synchronous-speed operation for as long as 45 min, with $1\frac{1}{2}$ in. Hg absolute exhaust pressure, the turbine generator can be loaded as fast as dry steam can be supplied.

2 Conservative starting and loading practice is determined by the rates at which temperatures throughout the machine will approach their steady-state values. Recommended starting times and loading rates are as follows:

Initial turbine temperature, deg F	Starting time, min	Loading rate, mw per min
150	50	1
450	20	3
750	10	5

The rate of throttle-steam-temperature increase should be made as constant as possible to reduce the temperature stress in the shells.

3 Loading or increase of throttle steam temperature can be done safely with respect to both expansion and temperature changes. With the turbine at any steady-state load, load can be increased to any other load at the rate of 5 mw per min at constant throttle temperature, or throttle temperature can be increased by 200 F at the rate of 500 F per hr at constant load.

4 Unloading or decrease of throttle-steam temperature must be considered carefully since the rotor contracts faster than the shell. The cooling gradients are usually low and uniform. As long as dry throttle steam is supplied, any amount of unloading can be done at the rate of 5 mw per min at constant throttle temperature, or throttle temperature can be dropped 200 F at the rate of 500 F per hr at constant load. The safest unloading procedure at any time consists of dropping all load instantly. During any unloading cycle, the throttle temperature should be held as high as possible.

5 The generator starting tests will be reported elsewhere.⁶ However, the test results show that there are no restrictions on starting time or loading rate of the generators, although it is recommended in the interests of longer life and lower maintenance that the main-generator field be preheated with a 850-amp current for 20 min immediately prior to operation at speeds above 1200 rpm.

These recommendations for this turbine generator are consistent with those previously published by the turbine manufacturer.^{6,7} However, initial turbine temperature is now taken into account and the recommendations are supported by specific test data.

After the remaining tests have been completed and analyzed, it is expected that these recommendations can be changed in the direction of higher rates of loading or temperature change. In interpreting these load rates for comparison to other machines, they should be compared on the basis of per cent of rated load.

The tests show that the Essex Unit No. 1 turbine generator is performing in accordance with design expectations both with respect to operation during transients and economy.⁸ Both the manufacturer and the operating company are well satisfied with the performance of the machine and its service record.

Appendix

THERMOCOUPLE NOMENCLATURE

The thermocouple locations are shown in Figs. 3 and 4. Designation of each couple has been made so that its approximate location can be deduced. The first letter indicates the inner or outer shell. The second and third letters indicate location on the shell. The number indicates longitudinal position starting at the high-pressure end. The meaning of each letter is given as follows:

⁶ Discussion by G. B. Warren, Supplement to Trans. AIEE, June, 1942, pp. 398-399.

⁷ "Steam Plant Performance on Fluctuating Loads—Part IV—Suitability of Modern Turbine Units," by E. E. Parker and C. W. Elston, Electric Light and Power, Chicago, Ill., April, 1949.

⁸ "Heat Rate Tests Results of the 100,000-Kw Essex Turbine Generator," by Vinal S. Renton and Stanford Neal, to be published in this issue of the Transactions, pp. 285-290.

- I Inner shell (or inside, if last letter)
- O Outer shell
- U Upper half
- L Lower half (or left side, if last letter)
- R Right side
- F Flange
- B Bolt
- C Steam chest

As an example, OU3R would indicate that the couple was in the outer shell, upper half, third position from the high-pressure end, and on the right side.

INSTRUMENTS AND THEIR APPLICATION

The special data required for this test were furnished by 4 expansion indicators and 40 thermocouples. All other data were taken from station instruments. These were the net load, steam pressure and temperature at the throttle, crossover, and exhaust hood, camshaft position, eccentricity of the shaft, vibration at each of the five main bearings, and turbine speed. The exhaust steam temperature was measured with three thermometers in the corners of the hood just above the horizontal joint. The exhaust pressures were measured in the plane of the exhaust-hood discharge.

The expansions were obtained by measuring the change in a magnetic circuit as the distance between the two pertinent parts changed. The instruments were the standard type usually supplied with General Electric Company turbines and were located at the positions shown in Fig. 2. One indicator was installed at the front bearing standard to measure the total expansion of the turbine shell from the exhaust hood to the front bearing standard. The No. 1 differential indicator was mounted at the coupling between the high- and low-pressure turbines and measured the difference in high-pressure-turbine rotor and shell expansion. That difference was measured from the thrust bearing which is located in the front bearing standard. The No. 2 differential indicator was mounted near the coupling between the turbine

and the generator and measured the difference in expansion of the entire turbine rotor and shell from thrust bearing to generator coupling. The No. 3 differential indicator was mounted at the coupling between the main and house generators and measured the movement of the turbine and generator shafts with respect to the foundation.

The difference between the indications of No. 1 and No. 2 is the difference in expansion of the low-pressure-turbine rotor and the exhaust hood. Since both the No. 2 and No. 3 indicators are essentially mounted on the foundation, the difference between their indications is the thermal expansion of the main-generator rotor less its elastic contraction in the longitudinal direction at speed relative to the foundation. When the expansion of the foundation is added to that difference, it is possible to deduce the average temperature of the rotor with a good degree of accuracy. The maximum thermal change in length of the generator foundation was small and was about 0.018 in. between room temperature and that corresponding to steady state, full load.

The No. 1 expansion indicator was in the exhaust hood in a steam atmosphere which occasionally reached 230 F, but no trouble was experienced for that reason. The other three indicators were in air at room temperature. The accuracy of the expansion measurement is believed to be from 0.002 to 0.004 in. No. 1 and the shell indicators were calibrated in place. No. 2 and No. 3 were calibrated before installation.

The shell temperatures were measured with 40 chromel-alumel thermocouples which were covered with silicone-varnish-impregnated glass insulation and were 80 ft long. The high-temperature ends of the couples were enclosed in stainless-steel tubing, and the junction of each couple was brazed to the tube, making a steamtight joint as shown in Fig. 18(A). The method of attachment of the couple to the shell is shown in Fig. 18(B). Fig. 18(C) shows the steamtight seal at the outer shell. The seal operated between steam conditions of 790 F, 400 psia and atmosphere. The steel sheath of each couple was brazed individually to the sealing diaphragm. The connecting pipe was made long enough

FIG. 18 DETAILS OF THERMOCOUPLE CONSTRUCTION AND INSTALLATION

to project through the turbine lagging so that the brazed assembly connections could be inspected or serviced. For protection of the fragile insulation, the couples were enclosed in a flexible steel sheath from the connection at the turbine to the potentiometer terminal board.

It was considered desirable to measure the temperature of the inner and outer surfaces of the inner shell at the first stage to determine the stresses due to unequal temperatures. The method of measuring the inner surface temperature is shown in Fig. 18(D). The couple was inserted through the hole in the shell and brazed to the cylindrical plug. The assembly was then pulled back into the shell, and the plug was peened in place. This construction was rugged and has given no trouble. The bolt and flange couples are shown in Fig. 18(E). All thermocouple potentials were measured by a self-balancing direct-reading potentiometer, which printed the temperatures at 4-sec intervals.

The couples were calibrated before installation, and the potentiometer was frequently checked during the progress of the test. It was expected that the thermocouples and potentiometer have a combined error of less than 4 F.

Some troubles were experienced during the 14 months of operation, and four of the couples are now open-circuited. Based upon this experience, it is believed that a couple can be made which will give accurate temperature readings for several years.

ACKNOWLEDGMENT

The authors express their appreciation to Messrs. E. M. Kratz and J. E. Phillips who were largely responsible for the instrumentation, testing, and evaluation of the data, and Messrs. H. G. Burk and J. Allhusen who supervised the operation of the unit during the tests.

Discussion

J. C. FALKNER.³ The tests on the Essex machine have confirmed the Consolidated Edison Company's tests on quick starting. That loading rates from 3.5 to 5 mw per min are safe is one of the most important conclusions of these tests, as many times we are faced with the necessity of loading machines rapidly to take care of sudden dark clouds, or thunderstorms. As the temperature of our high-pressure units after a 6- to 8-hr shutdown will be at 700 to 800 F, the rate of loading as shown by the paper should be as fast as desirable.

The Consolidated Edison Company of New York, like many other operating companies, had for years followed operating instructions given by the manufacturers as to how fast a turbine should be started, loaded, and what rate of steam-temperature change could be made safely during this starting and loading. In April, 1946, the company, pressed by steam conditions, departed from the manufacturers' instructions and began quick starting of high-pressure topping units. Since that time over 200 quick starts have been made, and there has not been a single instance where trouble developed during a start. There is every indication that the method is much better than that originally given by the manufacturers. However, after quick starting, a limitation of 100 F per hr rate of temperature change was maintained during loading. Loading rates have been held to values of $1/2$ to 1 mw per min after an initial loading of 4 mw. If the initial temperature of the turbine casing is 150 F or more lower than the steam temperature, the start is made at a slower rate. An hour is usually allowed for a start under these conditions.

The Consolidated Edison Company opened one of the topping

turbines at Waterside after operating 46,000 hr between November, 1942, and August, 1948. During this time there were 32 quick starts of approximately 15 min each, 74 water washes to wash off the phosphates, and four caustic washes to remove silica scale from the buckets. The machine was found in excellent condition, thus proving beyond any doubt that quick starting had not been injurious to the mechanical structure of the unit.

The quick starting of the turbines at Waterside led to trials at Sherman Creek Station, but conditions there were different as there is only one boiler per unit, while at Waterside there are two per unit with only one of the two boilers being used for starting. Therefore, temperatures as high as 700-750 F can easily be had on the starts at Waterside. On the 1,000,000 lb of steam per hr boiler at Sherman Creek, however, the steam temperature could not be brought over 500 F until a few minutes after starting. This meant that for a 6- to 8-hr shutdown the turbine metal temperature had to be reduced deliberately just before shutdown so that the initial steam temperature on the start would not cause a sudden drop and then a quick rise in cylinder temperature. In an effort to increase this initial steam temperature four oil burners were installed, high up in the furnace and pointed directly at the superheater. The results of typical quick starts with and without these oil burners are shown in Fig. 19 herewith.

In the start with oil burners the initial steam-chest temperature was allowed to be much higher than had been the usual practice, or 720 F, and the rolling time was cut down to 10 min. The turbine metal temperature drop was 50 F from 720 F to 670 F, and the rise was 100 F in 23 min, and only 150 F in the first hour. However, the steam temperature at the start was still only about 20 F above saturation, despite the use of the oil burners, and this temperature increased rapidly only after the throttle was opened, rising 105 F in the first 5 min. At the present time an additional by-pass around the topping turbine to the low-pressure machines is being designed so that the superheater will be cleared of water and the desired steam temperature will be obtained before opening the throttle. When this is installed the problem of steam-temperature control during starting will have been solved.

One of the latest and most important supervisory instruments used on turbine generators is the differential-expansion recorder which shows continuously the relative axial position of the cylinder and spindle and warns the operator of danger from an axial rub due to the spindle shrinking too fast in reference to the cylinder. In the paper the authors demonstrate that the differential-expansion recorder shows very little differential motion between spindle and cylinder when the turbine shell metal temperatures are between 400 and 450 F and the steam being admitted is at 700 to 750 F. This small relative motion is probably due to the fact that the heat in the steam is being dissipated and its temperature degraded while passing through the throttle and governor valve, and steam-chest structure.

Consolidated Edison Company, after the success of quick starting of topping turbines, tried the method on a 375-psi, 700 F, 160,000-kw tandem-compound condensing unit, and also on a 185-psi, 500 F, single-cylinder, 60,000-kw condensing unit. These trials were as successful as with the topping units, starting time being lowered on the large machines from $1 1/2$ hr to 20 min, and on the smaller machines from $1 1/2$ hr to 15 min. A decided improvement was obtained at the exhaust end of both units by lowering exhaust end temperatures immediately after the last-stage wheels by as much as 75 F to 100 F.

The Consolidated Edison Company expects to apply the quick-starting technique to all topping and condensing units on the system, and thereby realize an estimated annual saving of \$250,000.

In addition to the operating saving just mentioned, there are

³ Manager, Electric Production Department, Consolidated Edison Company, New York, N. Y.

FIG. 19 RESULTS OF QUICK STARTS WITH AND WITHOUT AUXILIARY OIL BURNERS

many practical operating advantages which result from quick starting. A notable instance occurred on August 27, 1948, when the Manhattan Cooper Square network was de-energized because of failures of generator cables in Waterside No. 2, causing a simultaneous outage of three out of the four topping units in this station. As soon as the first generator cables were temporarily repaired on Unit No. 4, this machine was brought up to speed and was generating power in less than 15 min and the network was re-energized. If the old original 3-hr start had still been in vogue at the time, the network would have remained out of service at least $2\frac{1}{2}$ hr longer.

The short starting time relieves the man-power problem in the turbine room of each station during the start-up period. With the quick-starting technique perfected it is possible to put machines in service one after the other with fewer men, who can concentrate on one machine instead of on several.

With the potentialities of quick starting of large high-pressure turbine generators fully realized, the Consolidated Edison Company is now focusing its thoughts on quick starting of high-pressure boilers after week-end shutdowns. We think that it will be possible to start such boilers from cold and have them up to full pressure in 1 hr or less. Test work is being planned at present to develop the details of such high-pressure-boiler quick-start procedure and, if expectations are realized, it is felt that the economical advantages of the integrated quick starting of boilers and turbines will have been fully exploited. However, we believe that fast shutdown and quick starting of high-temperature high-pressure boilers will be best accomplished when an all-welded construction is used to join waterwall and generating tubes to their headers and drums.

H. H. POOR.¹⁰ To obtain information on boiler performance during rapid load swings, and to investigate the permissible rate of load pickup on a hot boiler, the writer's company participated in the last three load-dump and quick-pickup tests in the program at Essex Station described in the paper.

¹⁰ Staff Engineer, The Babcock & Wilcox Company, New York, N. Y. Mem. ASME.

Fig. 20 of this discussion shows a sectional side elevation of the steam-generating unit, which is a B&W radiant boiler designed to deliver 900,000 lb per hr of steam continuously at 1350 psi and 985 F from feedwater at 455 F, with a 4-hr peak load of 1,000,000 lb per hr. Twelve circular burners, arranged for either pulverized-coal or oil firing, deliver fuel to the slag-tap furnace. The burner region of the furnace is constructed of close-spaced tubes fully studded and covered with plastic chrome ore; the remaining upper portion of the furnace is of bare tube-to-tube construction. The furnace is divided by a central water-cooled division wall to provide more cooling surface in the furnace, without increasing furnace volume, than would be possible without such a wall. There is a boiler screen of three half-rows and four full rows of boiler tubes, two-stage pendant superheater with interstage spray attenuation, economizer, and air heater.

During the tests oil was fired because of greater operating flexibility, as compared with pulverized-coal firing. The boiler master controller, feedwater flow rate, fuel-oil flow rate, induced-draft fans, and forced-draft fans were on hand control; the spray attenuators were on full-automatic control. The feed pumps were on automatic control, but during load pickup were adjusted manually. Operators were stationed at the burners in order to remove the atomizers from service or put them back in service as rapidly as possible.

The last test was the most interesting because of the very rapid increase in load after 15 min at no load, following the full-load trip-out. As shown in Fig. 21 herewith, the trip-out took place at 11:00 a.m. when the boiler was delivering 970,000 lb per hr. The steam flow dropped immediately to the quantity necessary to roll the turbine at rated speed under no load (this was a reading of 70,000 lb per hr on the steam-flow chart). After $14\frac{1}{2}$ min, load pickup was started by an initial load increase of about 50,000 kw, and a steam flow of 920,000 lb per hr was regained in $3\frac{1}{2}$ min.

The drum pressure just before the trip-out was 1400 psi. When the steam flow was cut off, the superheater-outlet pressure rose at once, and the lowest set valve popped about 1 sec after the trip-out. All three superheater-outlet safety valves and some or

FIG. 20 BABCOCK & WILCOX RADIANT BOILER, ESSEX GENERATING STATION, PUBLIC SERVICE ELECTRIC & GAS COMPANY, NEWARK, N. J.

all of the drum safety valves opened, relieving the pressure as indicated in Fig. 21. The last valve closed a little more than 7 min after trip-out. The heat supplied by the two oil lighters remaining in service was sufficient to raise the steam pressure so that the low set valve reopened 10 min after trip-out at a pressure of 1370 psi, and reseated $2\frac{1}{2}$ min later at 1340 psi. When the load was applied, the drum pressure dropped to a minimum of 1230 psi, leveled out at 1250 psi for some time, and then climbed back to normal operating range.

Water level was measured by the panel-board recorder and was checked during the time that the water was visible in the gage glass by an observer stationed at the glass. At trip-out the water level dropped from $+1\frac{1}{2}$ in. to -13 in., but had returned to the

FIG. 21 RECORDS TAKEN DURING TRIP-OUT TEST

bottom of the gage glass 6 in. below the drum center line at the end of 1 min. The water level was held at 5 in. below the drum center line when the load pickup was approached. When the first block of load (approximately 50,000 kw) was applied to the turbine and the steam flow jumped from practically zero to 550,000 lb per hr, the water level rose 14 in. to a level 9 in. above the drum center line. The load was held at this value for about 2 min, during which time the drum level came back to -4 in., remaining in sight in the gage glass, except momentarily, during the remainder of the load pickup.

As a check for carry-over, saturated steam was taken through a sampling nozzle located in the center saturated-steam connection from the top of the drum, and passed through a cooling coil directly into a conductivity cell, with no attempt to remove dissolved gases. Before the trip-out the conductivity-cell indication corresponded to a solids content of 0.9 ppm. After the trip-out the indication increased to 1.0 ppm and finally to slightly above 1.0 ppm. There was no sign of carry-over increase when the load was picked up, despite the rise in water level, and, after full-load steam flow had been reached, the indicated solids content gradually decreased to less than 0.7 ppm.

Gas temperature entering the superheater was measured by a high-velocity thermocouple located in the gas stream halfway between the roof and floor at the superheater inlet, 10 ft from the right side wall. The gas temperature dropped from 2100 F be-

FIG. 22 RECORD OF CONDITIONS DURING AND AFTER TRIP-OUT

fore the trip-out to 1100 F in 1 min, and then drifted down in irregular fashion to 800 F during the low-load period. When load was resumed the gas temperature rose again to 2100 F.

Steam temperature at the turbine throttle was approximated by a bare 22-gage iron-constantan thermocouple inserted in an idle thermometer well at the turbine inlet. Due to the thermal inertia of the thermometer-well assembly, the temperature reading did not follow the steam temperature very closely. The steam temperature indication before the trip-out was 960 F, and during the no-load period slowly drifted down to 900 F. During the load pickup, a large quantity of saturated steam was passed through the superheater before the normal superheater absorption rate had been re-established, with the result that the steam temperature indication dropped to 850 F during load pickup. Then, as superheater absorption returned to normal the steam temperature climbed to 1000 F.

In so far as the boiler proper was concerned the limiting factor with respect to rate of load pickup was water level in the drum. Under the condition of test the rate of load increase was approximately 240,000 lb per hr per min; as a result of these tests we conclude that with optimum regulation and careful co-ordination of the feedwater with the rate of load increase, it would be possible to bring this boiler from no load to full load in somewhat less than 3 min, at a rate in excess of 300,000 lb per hr per min, without raising the water level more than 10 in. above the drum center line, and without increasing the solids content of the steam.

AUTHORS' CLOSURE

The authors wish to emphasize again that the rates of loading of 5 mw per min should be considered as applying only to this size machine and should be expressed as a percentage of rated machine capacity when these results are interpreted as applying to machines of different construction and capacity.

Mr. Falkner's use of burners located high in the boiler to give high steam temperatures at starting is a very interesting and apparently necessary development and should make safer and more practical the starting of a turbine after a relatively short shutdown.

One means of reducing the thermal stresses during fast loading is by holding the temperature of the steam high while the unit is operating in spinning reserve. Since most boilers have a drooping characteristic, the same high location of burners may be desirable when a turbine is held as spinning reserve. It is understood that some West Coast power companies are investigating this

procedure. It is to be understood that the higher throttle temperatures at low loads may require slightly higher minimum loads to maintain low exhaust-hood temperatures.

The annual saving of \$250,000, as quoted by Mr. Falkner, is impressive enough to justify the large amount of experiment necessary to establish the optimum starting and loading rates. The discussions of both Mr. Falkner and Mr. Poor illustrate the necessity of considering starting and loading the entire power plant, rather than the turbine, boiler, or auxiliaries alone. Mr. Poor's discussion also indicates a direction for boiler design if fast pickup of load is made a requirement.

A study of the temperature data taken by Mr. Falkner and others shows that quick starting of a hot turbine should not impose undesirable stresses on the machine when the quick starting is made under proper conditions and supervision. The inspection of the Consolidated Edison Company turbines, showing that a large number of quick starts had been made with no damage or increased maintenance, confirms this study. However, quick starting is by no means a universal panacea for all

starting or loading difficulties. There is no substitute for close mechanical supervision of any piece of machinery during such times. If anything, supervision during rapid starting and loading is even more important than at other times.

A primary requirement in starting and loading is that thermal stresses should be held to allowable limits. This involves the consideration of steam and metal temperatures and the heat-transfer coefficients. After the allowable limits for different material and different type of construction have been established by experience over a number of years, it will then be possible to establish starting times and loading rates for the allowable limits of thermal stress. It is probable that the loading rates will not be uniform over the complete load range of the machine and will be affected by the initial conditions of throttle steam and metal temperatures, as well as the conditions of starting. With further tests made possible by the co-operation of the operators and the manufacturers, further knowledge of this subject will be obtained and power-generating equipment may be operated nearer the point of its greatest usefulness.

Fig. 1 DIAGRAM OF CYCLE AND LOCATION OF INSTRUMENTS

Heat-Rate Test Results of the 100,000-Kw Essex Turbine Generator

By VINAL S. RENTON¹ AND STANFORD NEAL²

A 3600-rpm, tandem compound, 100,000-kw turbine generator was recently installed at the Essex Generating Station of the Public Service Electric and Gas Company of New Jersey. Since it was, at that time, the largest machine of its type ever built, the first of a new class, and had initial steam conditions of 1250 psig and 1000 F, careful and extensive heat-rate tests were made jointly by the operating company and the manufacturer. The paper presents the results of the tests as an example of progress made in power-generating equipment.

INTRODUCTION

ON December 18, 1947, the largest 3600-rpm, tandem-compound steam turbine-generator ever built up to that time was placed in service as No. 1 unit at the Essex Generating Station of the Public Service Electric and Gas Com-

¹ Engineer, Electric Engineering Department, Public Service Electric and Gas Company, Newark, N. J. Mem. ASME.

Contributed by the Power Division and presented at the Semi-Annual Meeting, San Francisco, Calif., June 27-30, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-SA-19.

pany, Newark, N. J. Since it was the first of a new class of units for the manufacturer and the operating company, extensive tests were made to determine its heat rate and operating characteristics. The operating characteristics are reported in a separate paper.³

The heat-rate tests, with which this paper deals, were made in the period from February 14 to February 24, 1948, jointly by the Testing Laboratory of the Public Service Electric and Gas Company and the Turbine Engineering Division of the General Electric Company.

Results of the test were consistent with and slightly better than the guarantees. They indicate that this machine, of advanced design performs in accordance with anticipations.

CYCLE AND TURBINE DESIGN

The turbine generator with its unit boiler, condenser, and auxiliaries, was designed to fit into the space occupied by the existing No. 1 unit, rated at 20 mw, which had been installed in 1915. The specifications for the new No. 1 unit called for a highly efficient cycle which was to have its best heat rate at loads between 70 and 90 mw.

The feedwater-heating arrangement is shown in Fig. 1. It is believed that this is the first time in this country that as many

³ "Operating Characteristics of the 100,000-Kw Essex Turbine Generator," by Stanford Neal and Vinal S. Renton, published in this issue of the Transactions, pages 267-284.

as eight stages of feedwater heating have been used for one turbine. The heater system is also unusual in that the drains are cascaded, then passed through a drain cooler and to the hot well, where deaeration is accomplished.

As shown in Fig. 1, most of the losses are used to heat condensate. For conditions of high turbine exhaust pressure with the resulting high temperature of the condensate, a cooler is provided to reduce the condensate temperature for cooling the auxiliaries.

DESCRIPTION OF THE TURBINE GENERATOR

The semisection of the turbine is shown in Fig. 2. A mechanical description is reported elsewhere,⁴ and the following discussion is limited to points pertinent to a study of the heat-rate results.

The tandem-compound turbine has a nominal rating of 100,000 kw, and the steam conditions are 1250 psig 1000 F. The high-pressure section has 19 stages with extraction connections from the 7th, 10th, 13th, 16th, and 19th stages. The double-flow low-pressure section is on the same shaft and has 5 stages with extraction connections from each of the two 20th, 21st, and 22nd stages.

The three feedwater heaters supplied, with steam from the three latter extractions, are placed horizontally in the condenser neck and directly under the low-pressure turbine to conserve space and reduce the length of the extraction piping. Model tests were made jointly by the manufacturers of the turbine and condenser to determine the best location of the heaters. The 23rd and 24th-stage moisture catchers are drained to the hot well.

Steam flow and load are controlled by eight primary valves which admit steam to the first stage, and four stage valves which by-pass steam from the discharge of the 1st stage to the inlet of the 4th stage. The valving sequence is arranged so that seven of the primary valves open consecutively for the first seven admissions. The four stage valves are next opened together for

the 8th admission, and the eighth primary valve is opened for the 9th admission.

The shaft of the high-pressure turbine is sealed by a labyrinth packing and an impeller-type water seal. The labyrinth packing at the high-pressure end has three sections with leakage steam from the 1st section going through the space between the inner and outer turbine shells and out to the 10th-stage heater. The leakage steam from the second section is piped to the 16th-stage heater, and that from the third section to the 21st-stage heater. The labyrinth packing at the low-pressure end has only one section, which is piped to the 21st-stage heater. The shaft of the low-pressure turbine has only impeller-type water seals.

The main generator is rated 111,765 kva at 0.85 power factor, with 15 psig hydrogen pressure, and 117,647 kva at 0.85 power factor with 25 psig hydrogen pressure. The house or auxiliary generator is air cooled and rated at 7500 kw at 0.80 power factor. Separate motor-driven exciters supply the field electrical requirements.

The turbine and the two generators are coupled solidly to one shaft, and the unit has an over-all length of 77 ft, 7 1/2 in. and weighs 1,120,000 lb.

MOISTURE REMOVAL

The quantity of drain flow was calculated by heat balances around each heater individually. Since all of the heater drains were cascaded through a drain cooler to the condenser, the quantity of total drain flow also was calculated by a heat balance at the drain cooler. The drain flow, so calculated, was found to be consistently and significantly higher than the sum of the calculated extraction steam flows to the eight heaters. That difference was considered to be the quantity of moisture discharged from the turbine into the extraction pipes and showed a high effectiveness of the moisture catchers. The amount of moisture thus indicated as removed in the wet extraction stages was about 10,000 to 12,000 lb of water per hr and was nearly constant irrespective of load. The amount of moisture removed from the 23rd-stage and the 24th-stage diaphragm was expected to be large but was not measured. An examination of the last-stage

FIG. 2 SEMISECTION OF ESSEX NO. 1 UNIT TURBINE GENERATOR

⁴ "The Design of Seward Generating Station and No. 1 Unit at Essex Station, Public Service Electric and Gas Company," by F. P. Fairchild, published in this issue of the Transactions, pages 247-265.

buckets after 14 months of service confirmed this assumption since little erosion had occurred.

HEAT-RATE RESULTS

The heat rate of the turbine generator is defined as that quantity of heat supplied by the boiler (and the boiler feed and condensate pumps) necessary to produce 1 net kwhr of electricity. The net kilowatt-hour output is defined as the output at the terminals of the two generators minus the electrical inputs to the two generator fields.

Since the steam conditions and heater performance were not the same in every test, the test results have been corrected to a standard cycle to provide a uniform basis of comparison. The standard cycle differs from the test cycle principally in that:

- 1 The initial steam conditions were 1250 psig and 1000 F.
- 2 Exhaust pressures were 1.00 in., 1.50 in., 2.50 in., and 3.50 in. Hg abs.
- 3 Heater terminal differences and extraction-pipe pressure drops were assumed to be the same as in the turbine specification.
- 4 Attenuator flow was zero. (The attenuator was used only in 7 test points.)

The standard extraction cycle heat rates, based on test performance, are shown in Fig. 3 as a function of load for the four exhaust pressures. The points in Fig. 3 have been connected

by valve loops, the shapes of which have been determined by previous tests on other turbines. The rise in heat rate at loads above 93 mw is caused by the opening of the internal stage valves which provide a by-pass for the steam flow around the 2nd and 3rd stages. The heat-rate curve at 1.50 in. Hg exhaust pressure is well located with eleven points, but it should be noted that the curves at 1.00 in., 2.50 in., and 3.50 in. Hg are drawn from only three test points with the shape determined by the 1.50-in. curve.

The standard extraction cycle throttle and condenser steam rates based on test performance are shown in Fig. 4. It may seem surprising that the throttle steam rate is about 4 per cent better at 35 mw than at 117 mw while the heat rate is about 9 per cent poorer at the lower loads. This apparent inconsistency is explained readily since the amount of steam extracted for feed-water heating changes from about 22 per cent to 32 per cent over the same range of load. The larger percentage of condenser steam flow at 35 mw has the effect of reducing the amount of throttle steam per kilowatt-hour at the expense of a less efficient cycle with its higher heat rate. This example shows that a low throttle steam rate is not necessarily compatible with a low heat rate. Had this turbine been operated nonextracting, the steam rate would have been the same for both throttle and condenser flows and would have a value between the two sets of curves shown in the figure. As a matter of interest, the feed-

FIG. 3 HEAT RATE OF ESSEX NO. 1 UNIT TURBINE GENERATOR

FIG. 4 THROTTLE AND CONDENSER STEAM RATES OF ESSEX UNIT NO. 1 TURBINE GENERATOR

water temperature leaving the last heater was 477 F at the highest load.

ACCURACY OF THE TESTS

Extreme care was taken in the isolation of the unit, selection, installation, and calibration of the instruments, and constancy of test conditions. It was expected that the absolute accuracy would be about $\frac{1}{2}$ per cent, and the reproducibility somewhat better. The one check point at 93 mw differs from the first point by about 0.15 per cent. Since one point was made at the beginning and the other near the end of the test, there was no appreciable change of performance of the unit during test. There was no evidence of deposits in the steam path either by inspection or from unit performance.

GENERATOR TEST

The results of the generator pre-heating test will be reported elsewhere,⁸ and will not be described here. The generator losses were of the magnitude predicted by the manufacturer and the maximum temperatures were well within the design limits.

CONCLUSIONS

At the best point, which was at 93 mw load, and at an exhaust pressure of $1\frac{1}{2}$ in. Hg abs, the heat rate of the turbine-generator and feedwater heaters was found to be 8498 Btu per kw-hr for the standard cycle used to compare the test points. The corresponding thermal efficiency is 40.16 per cent. The standard cycle differed from the operating cycle by only a few tenths of a per cent.

At the rated exhaust pressure of $1\frac{1}{2}$ in. Hg abs, the heat rate averages 0.76 per cent better, and the best point is 1.4 per cent better than the guarantee.

Test data on the complete unit including boiler, turbine, feedwater heaters, and auxiliaries indicate an approximate over-all heat rate of 10,100 Btu per kw-hr at the most economical point during winter conditions. The corresponding thermal efficiency is 33.79 per cent. With 13,500 Btu per lb coal, that heat rate corresponds to the consumption of 0.75 lb of coal to produce 1 net kw-hr of electrical energy at generator terminals.

During the entire year of 1948, the station records show that the over-all unit heat rate was 10,500 Btu per kw-hr at an average load of 97,800 kw for each hour of operation.

Tests of the operating characteristics have demonstrated that the unit operates satisfactorily with fast starts and high loading rates. Several load-dump tests followed by fast pickup of load have been made with excellent performance.⁹

The Essex No. 1 Unit has satisfied both the owner and the manufacturer with respect to efficiency, operating characteristics, and service record.

ACKNOWLEDGMENTS

The authors express their appreciation for the valuable assistance of Messrs. E. M. Kratz, P. C. Van Nørdstrand, and M. W. Leonard in making the test and calculations.

Appendix

DESCRIPTION OF TEST INSTRUMENTS

The location of each of the test instruments is shown in Fig. 1.

All important temperatures were measured with chromel P-copric thermocouples inserted in wells. A few temperatures were measured with copper-copric thermocouples peened into pipe walls. All thermocouple potentials were measured with precision

potentiometers. The condensate temperatures at the generator coolers were measured with precision-grade mercury-in-glass thermometers. All thermocouples and thermometers were calibrated before and after the test, except for the peened couples which necessarily were destroyed in disassembly. Temperatures were read at ten-minute intervals, with the exception of those at the throttle and at the discharge from the highest feedwater heater, which were read every 5 min.

Pressures above 25 psia were measured with dead-weight gages, those between 5 psia and 25 psia with mercury-filled manometers open to atmosphere, and the condenser pressures were measured with mercury-filled absolute gages. All gages, weights, and manometers were checked carefully before the test. For convenience and accuracy, all turbine pressures at levels below 25 psia were measured with air-filled connecting pipes. This was accomplished by bleeding a very small amount of air into each pipe.

The condensate flow was measured with either a 4.335-in. or a 2.794-in.-diam flow nozzle. Both were calibrated before the test by Prof. S. R. Beidler. The pressure difference was indicated on a mercury-filled manometer read at one-minute intervals.

As an independent check on the throttle flow, the pressure difference across the uncalibrated station steam-flow nozzle was read at one-minute intervals. However, the water legs could not be determined accurately, and the measurements were not entirely consistent or reliable. This trouble was corrected after the test.

The condensate flows to the gland-seal tank and from the high-pressure-turbine packings were measured with displacement-type integrating water meters. The flow quantity was recorded every 15 minutes.

The flow to the attemperator was measured with the station nozzle. Since the flows were small, a dibromoethane (specific gravity = 2.17) filled manometer was used to indicate the pressure difference. Readings were made at five-minute intervals. The maximum attemperator flow was $3\frac{1}{2}$ per cent of the throttle flow.

Slag-tap and boiler-access door cooling flow was measured with a flow nozzle and a mercury-filled manometer. Readings were made at five-minute intervals.

The flow of condensate through the generator coolers was measured by thin-plate orifices. The coefficients were taken from the ASME fluid meters report.¹⁰ The pressure differences were indicated on mercury-filled manometers and read at five-minute intervals. In order to obtain a larger temperature difference across the main generator coolers at several test points, the arrangement of the station piping made it necessary to by-pass some condensate around the auxiliary-generator coolers, which prevented measurement of the cooler flow. For that reason, only a few loss measurements could be made on the auxiliary generator.

The leakage flow from the second section of the high-pressure packing was measured with a thin-plate orifice and a mercury-filled manometer, read at five-minute intervals. The leakage flow from the third section of the high-pressure packing was measured with an impact tube placed at the axis of the pipe and a pipe-wall static pressure tap. The pressure difference was indicated on a draft gage and read at five-minute intervals. This method of measuring the flow was necessary, since there was not sufficient pressure available for an orifice measurement.

Storages in the hot well and heaters were measured by observing calibrated sight glasses at 15-minute intervals.

The electrical output of each generator was measured with three single-phase indicating wattmeters read at one-minute intervals. The voltage and current in each phase were observed at two-minute intervals. The power input to the two fields was measured with voltmeters across the slip rings and milliammeters across shunts.

⁸ The generator preheating test is expected to be the subject of an AIEE paper by F. W. Gay and H. D. Taylor.

¹⁰ "Fluid Meters, Their Theory and Application," THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., fourth edition, 1937.

All ammeters, voltmeters, and wattmeters were calibrated before and after the test, and the current and potential transformers and the shunts were calibrated before the test. Check readings were made on the station integrating watt-hour meter which was especially equipped for the test with a high-speed register.

The tests followed the procedures outlined in the ASME Power Test Code. The Keenan and Keyes Steam Tables⁷ were used to determine steam properties.

Before each test, the turbine and heater piping was carefully checked to make certain that the cycle used was the one shown in Fig. 1, and to check the isolation of the unit. Isolation was made positive in every connecting pipe not necessary to the cycle by inserting blind gaskets between flanges or by closing two valves in series and opening a "telltale" drain valve between them to prove that no flow passed through the pipe. A single valve was used for only one connecting line which went to the condensate head or surge tank. That valve was checked carefully for tight closing before, during, and after the test. It was not possible to double-valve this line from the standpoint of safety.

The losses of each generator were obtained by measuring the temperature rise and quantity of the condensate used to cool the hydrogen in the main generator, and the air in the auxiliary generator. Since the four coolers in each generator are connected in parallel and it was practical to make only one flow measurement for each generator, it was necessary to adjust the flow through each cooler to give the same temperature rise. The hydrogen pressure was maintained at 15 psig, except for the two highest load points where it was held at 25 psig.

All test points except one ($8\frac{1}{2}$ admission point) were made at a valve-intercept point. That point occurs just prior to the opening of the next higher valve. The intercept point could be set accurately by opening the governor until all lost motion is taken up in the cam-and-roller assembly of the next higher valve. Since a force of only a few hundred pounds was necessary to take up this lost motion and several thousand pounds to lift the valve away from the seat, a check of the force on the roller with a pinch bar permitted accurate setting of the valve within 2 or 3 thousandths of an inch. This method is considered to be the most accurate since a measurement of valve lift will vary slightly with different loads on the turbine as the temperatures of the valve mechanism and steam chest change. The valve-roller tightness and the position of governing mechanism were checked several times during each test to make certain the valves had not changed position. The governor was very stable and it was not necessary to reset the valve position during any test. During tests, the governor was set on the "load limit" which essentially kept the governor from increasing the load but still left control for reducing the load by normal governor action if an emergency should arise.

For different tests, the exhaust pressure at the condenser neck was held at $3\frac{1}{2}$ in., $2\frac{1}{2}$ in., $1\frac{1}{2}$ in. Hg abs, and the lowest that could be obtained. For the higher values, the pressure was held by bleeding air from the atmosphere into the condenser. This method is simple and permits rapid and close control of the exhaust pressure. It was usually held within 0.01 in. Hg.

Tests were made with an exhaust pressure of $1\frac{1}{2}$ in. Hg abs at each of the nine admission points, at the $8\frac{1}{2}$ admission point, and a check test was made at the 7th admission. Other tests were made at exhaust pressures of $3\frac{1}{2}$ in., $2\frac{1}{2}$ in., and best (about 1.1 in.) at the 3rd, 5th, and 8th admission points.

The initial steam conditions were held as closely as possible to the rating of 1250 psig and 1000 F. At the lighter loads, the

boiler characteristics resulted in lower throttle temperatures. The throttle temperature usually was held constant within ± 10 F, and the throttle pressure within ± 10 psi.

All test points at exhaust pressures of $1\frac{1}{2}$ in. Hg abs were of 2-hr duration. Those at other exhaust pressures were 1-hr tests. To insure constant conditions, the load was set and held for 1 hr before the test period.

Discussion

ADOLF EGLI.* The 100,000-kw turbogenerator tested is a brilliant example of progress in modern power-generating equipment. As regards steam-power-cycle development, this unit represents the highest perfection to date of the regenerative-feed-heating cycle. The writer is struck by the elegant simplicity of the layout of the turbine flow path as well as with the completeness of the regeneration system applied.

The thermodynamic perfection attained is astounding; 40.16 per cent thermodynamic efficiency of the turbogenerator unit and 33.79 per cent thermal efficiency of the complete power unit, including boiler and auxiliaries, are indeed excellent values for a plant without the complication of a reheat cycle.

Remarkable is the combination of a flat heat-rate curve with great overload capacity which has been attained by a clever arrangement of throttle valves and by-pass valves regulating the throttle steam flow. Between maximum load and half maximum load, the heat rate (at $1\frac{1}{2}$ in. Hg back pressure) varies only 1.7 per cent, the best value being obtained midway between these points at the most important output. Even at 30 per cent maximum capacity, the heat rate is only 9.5 per cent above the best value.

Of the test instrumentation, the dead-weight gages used to measure the high steam pressures, are most intriguing to the writer.

Would the authors be in a position to give a detailed description of the design and operation of these gages? Precise measurement of the high steam pressures on a turbine in operation is a difficult problem, and the proper application of the dead-weight system would appear to be a valuable step in improving test precision.

In particular, the writer is also interested in the accuracy attained with condensate-flow-nozzle measurement.

A detailed heat balance of the unit tested would also be most informative. By publishing this information the manufacturer and the Public Service Electric and Gas Company would indeed render valuable service in the general advancement of the art of power generation.

AUTHORS' CLOSURE

The authors thank Professor Egli for his comments on the design and application of the Essex turbine generator.

It has been the practice of the authors' company to use dead-weight gages in the tests of steam turbines since they provide the most practical fundamental and accurate type of pressure measurement. It is difficult to use this type of gage when the pressure fluctuates rapidly. However, modern methods of pressure control in generating stations are sufficiently good to permit the use of deadweight gages. Although more work is involved in its installation and use, the increase in accuracy is believed to justify the additional time and expense. The area of our dead-weight-gage cylinder is 0.1250 sq in. (a diameter of about 0.4 in.) and is larger than the usual dead-weight gage or dead-weight-gage tester. The sensitivity of about $\frac{1}{2}$ in. of water and the practical advan-

⁷ "Thermodynamic Properties of Steam," by J. H. Keenan and F. G. Keyes, first edition, twelfth printing, John Wiley & Sons, Inc., New York, N. Y., 1946.

* Professor of Mechanical Engineering, Towne Scientific School, University of Pennsylvania, Philadelphia, Pa. Mem. ASME.

tage of free plunger travel is believed to outweigh the inconvenience of the correspondingly large weights.

The gages are oil-filled and, in steam-turbine tests, are usually operated with water-filled lines, necessitating the usual water-leg correction. In operation, the pan is loaded with weights until the pressure is balanced, the weight pan being rotated by hand to remove any friction effect. Arrangements have been used with the pan loaded with a spring or balance arrangement of about 10 psi capacity to avoid the use of small weights. Such devices have also been used for the control of pressure with the rotation of the plunger accomplished by an air turbine. The radial clearance between the cylinder and plunger is held to about 0.0001 in. and the parts are usually made of nitraloy with lapped surfaces.

There is a question as to whether the area of the cylinder or of the plunger or some intermediate value should be used. With these close fits, the error involved when an average area is used

cannot be more than about 0.05 per cent. Calibrations by the Bureau of Standards and others confirm this opinion.

The two nozzles used in this test were made by the Bailey Meter Company and installed with straightening vanes in a pipe of suitable length. The two assemblies were calibrated by Prof. S. R. Beitler and are believed to represent the true coefficient within ± 0.2 per cent. Each nozzle was used only in the Reynolds number range of constant value of the flow coefficient. The smaller nozzle was used in the Reynolds number range of 1,200,000 to 1,600,000, and the larger from 1,200,000 to 2,200,000. While these ranges require extrapolation of the calibration to somewhat higher values than could be reached in the calibration, that extrapolation was in the region of the constant value of the flow coefficient and is well justified by experience.

The addition of heat balances at three loads was considered when this paper was prepared, but it was decided to omit these items because of lack of space.

Frictional Characteristics of O-Rings With a Typical Hydraulic Fluid

By L. E. CHEYNEY,¹ W. J. MUELLER,² AND R. E. DUVAL,³ COLUMBUS, OHIO

O-ring packings employed in aircraft hydraulic systems are subject to numerous operating variables, which affect the friction involved in their operation. A method for studying the friction is described, and the effects of several variables—pressure, time delay, squeeze, stroke speed, ring size, and surface finish of the moving metal part—have been determined.

INTRODUCTION

DURING the past several years there has been a strong trend in the aircraft industry toward the use of hydraulic systems, as a result of increases in the size of planes, where the required forces prohibit manual operation of many controls. The hydraulic system has an advantage over other possible systems because it assists in the movement of controls, but it still maintains the "feel" which is considered highly desirable.

Among the small but important parts of a hydraulic system are the packings. Earlier systems in use for aircraft employed one or more of the well-known V-ring, U-cup, or compression-type packings. The O-ring is a fairly recent development in the packing field, which has been shown to have many advantages over the older types.

To prevent sticking of moving parts and excessive wear on packings, the friction between the moving parts and the packing should be held to a minimum. It would be expected that the early compression-type packings would cause high friction because of their design. O-rings offer an opportunity to reduce this friction because of a much smaller area of contact with the moving part.

Previous published work on the subject of friction is meager. Several recent articles (1, 2, 3, 4, 5, 6, 7, 8)³ give limited data concerning the effect on packing friction of various characteristics of the hydraulic system, while the general frictional characteristics of rubber are treated in some previous publications (9, 10, 11). While these articles cover a part of the field, some of them freely admit that there is much work yet to be done.

EXPERIMENTAL PROCEDURE

An apparatus was designed so that friction caused by an O-ring could be measured under controlled conditions, with one factor varied at a time. In the apparatus employed, an actuating rod was drawn through a stationary O-ring. Frictional forces were transmitted from the ring, through a bellows arrangement, to a recording engine indicator.

The entire apparatus could be considered as composed of several individual units as follows:

¹ Formerly Assistant Supervisor, Resin and Rubber Research, Battelle Memorial Institute.

² Research Engineer, Battelle Memorial Institute.

³ Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Rubber and Plastics Division and presented at the Annual Meeting, New York, N. Y., November 28–December 3, 1948, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 48—A-64.

1 The nucleus of the machine was a hydraulic press, to the ram of which was attached an actuating rod (SAE 4340 steel, Rockwell hardness 40 C). Ram speed of the machine could be varied from 85 to 300 ipm on the upstroke, and 60 to 215 ipm on the downstroke. A timing device was installed to allow an automatic variable time delay between strokes.

2 The hydraulic pressure unit consisted of a pump and reservoir with accessory equipment such as time switches, tubing, etc. The variable-flow pump employed was capable of producing 3000 psi fluid pressure. The oil reservoir, a large box made from steel plate, held about 50 gal of oil and was provided with cooling coils.

3 The assembly for holding the O-ring under fluid pressure consisted of a section of stainless-steel tubing with a cap screwed on each end. The end of each cap contained a hole, through which the actuating rod passed. One end of the tube was sealed by the O-ring, contained in a machined groove inside the cap. The other cap contained no packing but had a lap fit around the rod with a clearance of about 0.001 in. (The friction from this lap fit was found to be negligible.) The hydraulic pressure was applied to the inside of the sealed tube.

4 The friction-measuring unit consisted of a bellows connected to an engine indicator by means of copper tubing, the entire unit being filled with oil and sealed. The frictional force was transmitted from the ring to the bellows by a special cap, which in turn transmitted it through the oil to the recording engine indicator, which recorded the friction continuously.

In any work of this type the accuracy of test results should be considered. It is felt that the measuring unit is quite accurate because of its basic design. The spring on the engine indicator can be calibrated with dead weights and this is done at frequent intervals. A small error is involved in reading the engine indicator cards because a small distance between lines on the card corresponds to several pounds friction. This error is of the order of 3 or 4 lb maximum; it could probably be reduced if necessary by constructing a special micrometer-type scale for reading the cards. Assuming the measuring unit to be quite accurate, the accuracy of the work would then be limited only by the degree to which the friction would reproduce itself.

An effort was made to evaluate what were considered the more important variables, as indicated by previous work (1, 2, 3, 4). This study was concentrated upon one hydraulic fluid (Army-Navy Specification AN-VVO-366B). All of the work was performed using one typical ring size (-28 as described in Army-Navy Specification AN6227), except the study of ring-size effect. Testing was done at room temperature. All of the rings used in this study were aged in hydraulic fluid before testing, according to Army-Navy Specification AN-P-79.

EXPERIMENTAL RESULTS

Previously published data have recommended that the O-ring groove depth be 10 per cent less than the free diameter of the ring (6). The purpose of the shallow groove is to make certain that the ring is subjected to a positive squeeze at all times. This positive squeeze is necessary if the ring is to seal at low pressures where the pressure is not great enough to deform the ring and force it against the diametral clearance between the moving

FIG. 1 EFFECT OF SQUEEZE ON FRICTION
(2.8-3.2 microinches surface finish, 300 ipm stroke speed, 500 psi pressure.)

FIG. 2 EFFECT OF PRESSURE ON FRICTION
(2.8-3.2 microinches surface finish, 300 ipm stroke speed.)

and stationary parts. Army-Navy Specification AN-P-74 designates the minimum squeeze to be applied to an O-ring; this squeeze is approximately 10 per cent of the cross-section diameter of the ring.

Breakout- and running-friction determinations were made under various conditions of pressure and time delay, in addition to variation of squeeze. The result of a large number of tests shows that the running friction is largely independent of squeeze over the range covered. There is some tendency at higher pressures for the running friction to increase slightly with squeeze. A different situation exists in the case of breakout friction, where an increase in squeeze results in an increase in friction. Fig. 1 shows typical data of friction versus squeeze for running and breakout friction. The points shown are chosen as representative of about 2500 determinations. The range of results, as shown by the figure, is approximately ± 15 lb for the breakout friction and ± 8 lb for the running friction.

The effect of hydraulic pressure has been noted previously (1, 2). As there is a strong trend toward higher pressures in the newer aircraft systems, this is a very important factor. The effects of 500, 1000, and 1500 psi pressure were checked in this study. It was found that an increase in pressure resulted in a small increase in running friction and a large increase in breakout friction. Figs. 2 and 3 illustrate this point. The data shown here are typical of about 700 determinations. It can be seen that the accuracy is approximately ± 15 lb for the breakout friction and ± 10 lb for the running friction.

It has been generally felt that the breakout friction would be higher as time delay between strokes increased. Experimental results confirmed the original belief for time delays of less than 40 min. Time delays of more than 40 min, however, did not increase the friction appreciably.

FIG. 3 EFFECT OF PRESSURE ON FRICTION
(2.8-3.2 microinches surface finish, 300 ipm stroke speed.)

Running friction was not expected to change with time delay between strokes. In this case also, the experimental data confirmed the original belief. Fig. 4 shows data, typical of about 1600 determinations, on the effect of time delay on the two types of friction. The accuracy of reproduction is about ± 10 lb.

FIG. 4 EFFECT OF TIME DELAY ON FRICTION
(2.8-3.2 microinches surface finish, 300 ipm stroke speed, 1500 psi pressure.)

FIG. 5 EFFECT OF SURFACE FINISH ON FRICTION
(300 ipm stroke speed.)

The importance of roughness of the surface which rubs against the ring has been recognized by other investigators (1, 2). Army-Navy Specification AN-P-74 requires a surface finish (roughness) of 5-15 microinches root mean square (rms). (This is to be changed by eliminating the minimum requirement and retaining the 15-microinches rms maximum roughness.) In order to investigate this factor more thoroughly, a series of 4 rods was constructed. These rods were ground to finishes of 2.8-3.2, 6-8, 10-12, and 16-18 microinches rms. All four rods were evaluated with the same ring to eliminate any variability from that source.

These four rods represent a range of surface finishes not only covering, but also above and below the present specification limits. Fig. 5 shows typical curves for this series. It can be seen that there is a definite increase in friction with an increase in surface roughness.

An additional rod with a surface finish of 1.7-2.0 microinches rms was constructed and evaluated later in a manner similar to the four rods previously studied, although the same ring was not used. The data obtained for this rod are also included in Fig. 5 and show good agreement with the other values. The accuracy of these data is considered to be approximately ± 10 lb.

It has been reported that a chemical surface treatment was being used on some hydraulic parts. Several advantages were claimed for this treatment, particularly reduction of friction, because of better retention of an oil film on the surface. In order to investigate this point, a special rod was constructed and treated by the commercial process. This rod had a surface finish of 10 microinches rms before treatment and 30 microinches rms after treatment. This rod was included in the series showing the effect of surface finish on friction, Fig. 5. The frictional results obtained were apparently directly proportioned to the roughness of the finished rod.

A limited amount of work was done to determine the effect of stroke speed. Figs. 6 and 7 show these data. The running friction was almost independent of stroke speed over the range tested. An increase in breakout friction was noted with an increase in stroke speed at 1000 psi, but at other pressures the friction was independent of stroke speed. There are indications that factors other than stroke speed, for example, pressure, are more significant in determining the friction in a system.

The effect of ring size on friction has been reported by Pearl (2). This author showed the friction to be a function of pressure and projected area of ring exposed to pressure. The area of contact of a packing and moving surface would be expected to affect the amount of friction.

Four sizes of O-rings were given an evaluation to determine the effect of ring size. The ring sizes were —19, —23, —28, and —29 as described in Army-Navy Specification AN6227. The actual sizes are given in Table 1.

TABLE 1 SIZES OF O-RINGS

Ring	Cross-sectional diam., in.	ID, in.	OD, in.
—19	0.139	0.984	1.262
—23	0.139	1.234	1.512
—28	0.210	1.475	1.895
—29	0.210	1.600	2.020

The sizes were chosen to show the effect of diameter at constant cross section, using two different cross sections. Graphs of friction versus squeeze, at different conditions of pressure and time delay, where the data from all four rings were plotted on one graph, show that under some conditions one ring size gave the greatest friction while under other conditions another ring caused the greatest friction. Although the friction of all four rings followed the same general pattern, it could not be concluded that any one ring size consistently gave higher friction than another ring size, at least in the range of dimensions investigated.

Reproducibility of results has been checked in two different ways. One ring from each of several manufacturers was evaluated thoroughly and the comparative results recorded, then five rings from one manufacturer were evaluated in succession. Fig. 8 compares the reproducibility between rings from one manufacturer with that of rings from different manufacturers. It can be seen that the distribution of points in the two curves is very nearly the same, that is, reproducibility between rings of different manufacturers is approximately the same as reproducibility be-

FIG. 8 REPRODUCIBILITY OF FRICTION OF O-RINGS
(2.8-3.2 microinches surface finish, 300 ipm stroke speed, 40-min delay, 500 psi pressure.)

tween several rings from one manufacturer. It can also be seen that the friction curves for the different manufacturers' rings are approximately the same within the accuracy of our testing. From this it can be concluded that all of the manufacturers whose aircraft hydraulic packings have been checked-produce rings of similar frictional characteristics, although there are insufficient data to justify a general conclusion that all are the same.

SUMMARY

Certain design and operating variables in aircraft hydraulic systems have been studied in relation to friction.

It is possible to summarize the resulting data in a fairly comprehensive form. Table 2 summarizes the effect of the variables studied on breakout and running friction.

ACKNOWLEDGMENT

The work described in this paper was carried out in connection with a research project sponsored by the Bureau of Aeronautics, Navy Department. Any opinions expressed here are those of the authors and do not necessarily represent those of the Navy Department. Acknowledgment is also made of the assistance rendered by other Battelle personnel.

TABLE 2 VARIATION OF BREAKOUT AND RUNNING FRICTION WITH CHANGES IN HYDRAULIC SYSTEM

Design or operating change	Breakout friction	Effect	
		Running friction	
Increase squeeze.....	Increase	No effect at low pressure (500 psi). Slight increase at high pressure (1000, 1500 psi).	
Increase time delay between strokes.....	Increase	No effect	
Increase hydraulic pressure.....	Increase	Increase (slight)	
Increase roughness of moving rod.....	Increase	Increase

Discussion

G. E. DAVISSON.⁴ The authors are to be congratulated on the excellent work that is summarized in the paper. A short history of this testing program will reveal its vital importance.

History of Testing Program. During the last war the Army Air Force and Navy Bureau of Aeronautics added the winterization requirements, calling for operation of aircraft hydraulic equipment at temperatures from -65 to +160 F, to the AN Specifications covering this equipment. This requirement made obsolete all of the old components of hydraulic equipment that were designed for operation to a minimum temperature of -40 F. It also made necessary an intensive program of development and testing by the services and the aircraft industry. The use of the original winterized O-rings with AN-VV-O-366b winterized hydraulic fluid resulted in an epidemic of so-called spiral failures and other miscellaneous types of O-ring failures.

In 1944 the Technical Advisory Committee on Hydraulic System Materials was formed. This committee is composed of representatives of the two services, and the manufacturers of aircraft, of hydraulic fluid, of packings, of hose, and of miscellaneous hydraulic equipment. The function of this committee is to assist the services in their program to improve performance of aircraft hydraulic systems. The committee makes recommendations for and co-ordinates the results of tests made on O-rings, hydraulic fluid, and all types of hydraulic equipment by industry.

⁴ Walker Manufacturing Company, Racine, Wis.

As the result of a great deal of test and development work by the services and by manufacturers of aircraft hydraulic fluid and packings, with help and advice of the Technical Advisory Committee on Hydraulic System Materials, there had been by 1946, a gradual improvement in the quality of hydraulic fluid and packings and in the compatibility of one with the other. However, there was urgent need for a comprehensive study of the fundamentals of packing and fluid behavior, which neither the services nor industry was in a position to undertake. Battelle Memorial Institute was found to be the organization that could undertake such a study. Battelle initiated test programs for both the Air Force and the Navy, and personnel of Battelle, active in this work, were made honorary members of the Technical Advisory Committee.

The present paper is based upon data obtained in this testing program. This information is valuable because it helps to build a foundation of scientific facts which will permit the services and industry eventually to eliminate the causes of packing failures in aircraft hydraulic systems. A great deal of progress has been made on this program, but a lot remains to be done. However, continued co-operation between the organizations involved eventually will insure that our pilots will fly better safer aircraft.

O-Ring Friction in Industrial Applications. The Battelle tests were for typical aircraft installations. For industrial applications, automotive type of cylinder oil is used more frequently than AN-O-366 hydraulic fluid. This is due to its ready availability, especially for refilling the systems. There will be less friction when cylinder oil is used. In most cases an O-ring made from a special industrial compound will be required for use with automotive cylinder oils. Use of brass or aluminum for piston rods or cylinders in place of the SAE 4340 steel will increase the friction, all other variables being the same.

O-Ring Friction in Pneumatic Systems. The friction in well-lubricated aircraft and industrial pneumatic installations normally will run higher than in comparable hydraulic systems. Friction is extremely high on poorly lubricated pneumatic installations where O-ring packings are used. Normally, O-rings are not recommended in unlubricated pneumatic installations, due to the excessive friction and the resultant high percentage of ring failures.

B. P. GRAVES.⁵ O-rings properly applied, are quite effective in preventing leakage between sliding surfaces, at least for a time. The important question to consider is—"How long will they last?" The writer has been seeking for some time to find a reliable answer to this question within our own personal applications and research, or in any of the papers on the subject of O-rings which have come to hand.

In discussing this subject with many hydraulic engineers and users of hydraulic equipment, the life of sliding O-rings has been questioned seriously, and the consensus of opinion seems to be that their life is too short. So instead of presenting a discussion on this paper, the writer finds it almost necessary to question the authors as follows:

Can the life of O-rings be extended to a practicable degree by practical methods, or ordinary shop methods? Of particular interest to us would be the effect on life of O-rings, of such matters as relative smoothness of the sliding surfaces, the condition of the grooves into which these O-rings fit, the composition of the O-ring and its hardness, amount of initial compression, working pressures, and speed of oscillation.

The several questions sum up to this one particular issue—is the life of an O-ring to be measured by the number of starts, the total

⁵ Director of Design, Brown & Sharpe Manufacturing Company, Providence, R. I. Fellow ASME.

distance traveled, or is it mainly a question of time under pressure?

We are particularly interested in the O-ring application because it offers a tantalizing picture of extreme compactness, high initial efficiency, and economy.

Answers to the foregoing questions would be of great value to the application engineer and to the user.

L. S. LINDEROTH, JR.⁶ It is most interesting to note the indications of uniform performance of rings made by different manufacturers. The data in the curves of running and breakout friction should be very helpful to the design engineer.

If future work is contemplated to carry on and amplify these data the writer would like to suggest a series of experiments to determine the possible variation in friction with different rod materials such as chrome plate, stainless steel, nonferrous alloys, and so on. From the designer's point of view it would be helpful to have the friction expressed in terms of rod or cylinder circumference. It would also be helpful to know whether the present AN specifications on the O-ring material are optimum for all types of service. Personally, the writer believes that for industrial use a better material can be compounded, since for one thing the extreme temperature requirements of the AN specifications are seldom encountered.

He has often wondered whether a rod or cylinder surface could be made too smooth, and perhaps the results indicated in Fig. 5 of the paper, on the running friction of the 1.7-2.0 rms rod bears this out. Notice that the point indicates a higher friction than the extended curve.

Personal experience has indicated that long time delays, several days to several months in duration, give extreme breakout friction values. This paper does not indicate whether any experiments considerably over 40 min duration were made. This is an important factor as relating to storage life of completed units and deserves considerable attention.

Were the points on the various curves measured with the rod going in one direction only or were directions measured and recorded? If both directions were recorded was there a difference between frictions with a dry and an oily rod?

On the measurement of the breakout friction with variation in rod speed, does not acceleration play a larger part than change in friction? With the bellows, fluid, and engine indicator parts all having appreciable mass, some question may arise as to the accuracy of the measurement of nonstatic loads. It may be desirable in future experiments to use a measuring means independent of mass in the measuring instrumentalities.

All tests in this paper were carried on at room temperature, presumably 70 F. It has been the writer's experience that most operating equilibrium temperatures are on the order of 150 F, unless special cooling is introduced. It would be helpful to know what effect temperature would have on the running and breakout friction with the time delay starting at the elevated temperature.

B. R. TEREZ.⁷ The study of all packings used in aircraft hydraulic systems regarding their frictional behavior due to change in squeeze, time delay between strokes, pressure and roughness of moving surfaces has always been of the utmost need. For years the aircraft hydraulic designers and engineers have been searching for such useful data to improve the operation of their equipment by reducing over-all friction. The discussion covered in this paper gives a clear-cut analysis of the frictional characteristics of

O-rings, most commonly used in the aircraft industry at this time, and the authors along with the Bureau of Aeronautics, should be complimented for this presentation.

In almost all aircraft hydraulic-equipment design work, there are two major points or locations where friction data on packing installation is badly needed. These two points are rod-gland-seal installation; and piston-head-seal installation. It is also pointed out that most of the serious problems in industry are with seals which are installed at rod ends of cylinders, where the leakage can be detected very easily.

The authors have discussed the investigation of this gland seal very thoroughly. In the test setup employed by the authors the O-ring does not change position at the start of the stroke. In an actual aircraft piston-ring seal the O-ring is at the side of the groove next to the pressure prior to starting the stroke. Therefore the O-ring must move to the opposite side of the groove as the pressure is applied, and as the stroke starts. This test information and data may not correlate with actual service experiences on piston-head seals. It is believed that in actual operating conditions the breakout friction will be less due to the rolling of the O-ring before the actual starting of the stroke.

It is surprising that in no place in this paper is there mention of friction tests at zero or very low pressures. Installations with such requirements are common in the aircraft industry.

There is also no mention of friction of O-rings with the use of leather back-up rings. This is understandable because there is an increased amount of work and testing involved for such an investigation.

It is stated in the paper that in the range of dimensions investigated, there was no appreciable difference in friction due to O-ring sizes. It is hoped that this will not be misinterpreted or confusing to designers because there must be a difference in friction due to change in size of O-ring as friction should be directly proportional to contact area.

The information covered in this paper is very valuable to the aircraft industry and also to all industrial hydraulic applications. It is important that it is leading to the discovery of causes of failure and other phenomena which occur in hydraulic systems. It is suggested that the authors, in their final analysis of friction characteristics of O-rings, prepare a technical chart wherefrom hydraulic designers can pick friction information for their particular designs at a glance.

AUTHORS' CLOSURE

The authors wish to thank the critics for their remarks about the work. Mr. Davison's discussion of the background of the project is a fitting addition to this summary of facts. Many of the questions raised in the discussion are beyond the narrow scope of this paper, but are welcomed because they propose a rather logical course for further investigation. They introduce problems of fundamental importance to the hydraulics industry.

For all data reported, rod travel was in a direction opposite to the direction of applied working pressure. This is almost always the performance condition for rod seals when an hydraulic cylinder is operated. However, limited tests were made for the reverse case in which travel was in the direction of the applied working pressure. A "toe-stubbing" or high-frequency "stick-slip" type of friction was observed which was considered unworthy of analysis. Recent endurance-cycling tests at Battelle indicate that this application shortens O-ring life.

This study was confined to room temperatures which averaged about 90 F, but actually ranged from 60 to 115 F. This was dependent somewhat upon operating conditions, but mostly upon the season of the year. This factor is considered to be only a minor cause for the rather wide deviations reported. Inspection of the data and temperatures at which single measurements were

⁶ Professor of Mechanical Engineering, Iowa State College of Agriculture and Mechanic Arts, Ames, Iowa. Mem. ASME.

⁷ Project Engineer, Aircraft Development, Weatherhead Company, Cleveland, Ohio. Mem. ASME.

made seems to indicate that running and breakout friction increase slightly with temperature. This was not demonstrated conclusively, however.

In so far as packing life at higher temperatures is concerned, it is well known that rubber ages much more rapidly at higher temperatures. Consequently, an appreciably shorter packing life would be expected for an application involving temperatures in excess of that for which the packing was designed. AN-P-79 packings are designed for a maximum temperature of 160 F. Many commercial-type packings have been designed for still higher temperatures. An upper limit for rubber-type packings is believed to be in the range of 250 F.

Zero-pressure breakout friction was not included in the work reported here. However, a study of certain unreported data has shown that zero-pressure breakout may be determined by extrapolation to zero pressure of the values determined at 500, 1000, and 1500 psi, when the other factors remain constant. This method generally determines values within the deviation limits cited, but they are occasionally high by as much as 50 per cent.

Time delays in excess of 40 min., and O-ring installations with leather back-up rings were not studied. Early work at Battelle showed that time delays of several days gave only slightly greater breakout friction than that obtained for 40 min. The maximum delays reported are, therefore, approximately representative of the maximum breakout developed by O-rings during pressurized stand-by periods. Over a long period of time, for example, several months in a service installation, other factors such as permanent set and fouling of the extended rod, due to heat and dust exposure, would be expected to increase breakout friction a significant amount.

Variable acceleration, if it existed, was dependent upon stroke speed, due to the nature of the test machine. Therefore, it is believed legitimate to express breakout friction as a function of stroke speed in Fig. 7 of the paper. Recent measurements have shown that rod acceleration was in the order of 100 fps per sec. Therefore, a full-stroke speed of 300 ipm was reached within about 0.004 sec after start. Recent oscillograph-type measurements of friction, which correlate very well with the engine indicator-type measurements of friction reported in this paper, show that breakaway occurs during this acceleration period.

The mass of the bellows and engine indicator are believed to have introduced some inertia factor into the breakout results reported. However, very little displacement of these components during breakout was observed, making this factor a negligible one, in light of the deviations reported. The authors realize the need for a method of measuring breakout friction which would be totally independent of any inertia interference.

The initial position of the O-ring recently has been observed to vary unpredictably during the stand-by period. An initial static-friction pull on the rod due to pressurization of the O-ring alone has been seen to vary from zero to 5 lb. Considering the high-order acceleration involved during breakaway, this is believed to account for the large deviations in the breakout-friction results. This irreproducibility would, however, be characteristic of actual O-ring installations in hydraulic systems.

It was seen that running and breakout friction decreased with increased rod smoothness for the range of surface finishes studied.

Although two points at 1.7–2.0 microin. rms in Fig. 5 of the paper, are out of line and indicate higher friction, a different O-ring was tested for this surface finish. The reproducibility of friction between different O-rings is illustrated in Fig. 8, and could account for the deviations from the smooth curves drawn in Fig. 5.

Since the presentation of this paper, considerable effort has been directed toward determining the effect of O-ring size on friction, and correlating the accumulated data into technical design charts. In general, it was found that the smaller sizes developed less friction, as expected. The resultant data, however, could not be fitted into a correlation which could be extrapolated to all sizes. This was due to the large variability in our data, and also to many dimensional factors which were difficult to control closely. Running-friction characteristics were much more consistent than breakout friction, and appear capable of being resolved into such charts. More sensitive test methods will be required to do this, however.

It cannot be said that the present AN specifications represent the optimum in O-ring material. Instead, they represent the minimum requirements, which would enable United States military aircraft to operate anywhere in the world with the same hydraulic fluid and packings. In the development of materials to meet this broad objective, many compromises in physical properties had to be made. Oil resistance, for example, was sacrificed for low-temperature flexibility. O-rings with physical properties superior to AN compounds have been formulated for individual industrial applications, where low-temperature flexibility is not a problem and wider latitude exists in the choice of a hydraulic fluid.

The frictional characteristics of O-rings are believed indicative of their expected life in service, within limits. High breakout friction is evidence of extrusion, where the packing is more susceptible to "nipping" when the rod is actuated. O-ring packings will tend to wear away faster by abrasion when running friction is high. Endurance cycling tests show, however, that the wearing rate of the packings does not correlate strictly with O-ring life, though wear is proportional to the number of completed strokes. Further investigation revealed that strict definition and control of pressure-time characteristics is of utmost necessity in conducting life tests, and being able to predict how long the O-rings will last in service. Accurate measurement and close control of the pressure-time relations in hydraulic systems is a serious problem in itself. This will have to be solved before the effect of the finite packing properties on O-ring life can be determined.

TABLE 3 SUMMARY OF GLAND-DESIGN FACTORS

Type of application	Low pressure (500 psi)		High pressure (1500 psi)	
	Squeeze	Surface finish	Squeeze	Surface finish
Intermittent cycling (breakout friction is important)	Maintain as low as possible	Maintain as smooth as possible	Unimportant 10 to 16%	Unimportant in 2- to 11-microin. range
Continuous cycling (running friction is important)	Maintain as low as possible	Maintain as smooth as possible	Unimportant 10 to 16%	Maintain as smooth as possible

It is believed that the friction studies point out certain gland-design considerations which can be applied to lengthen O-ring life. These are summarized in Table 3 of this closure.

Strength-Variance Studies of Plastics

By W. J. GAILUS,¹ STEVEN YURENKA,² AND A. G. H. DIETZ³

Preliminary work of the plastics research program at the Massachusetts Institute of Technology, sponsored by the Plastic Materials Manufacturers Association is reported. A statistical study of the effect of pertinent variables likely to be encountered in gathering mechanical data from a representative system of plastics (polymethyl methacrylate) is described. Effect of manufacturer, rate of test, and nature of test specimen is reported.

INTRODUCTION

BASIC to the plastics research program reported in this paper was the need for a clear understanding of the variables likely to be important and for a rather complete knowledge, from a physical viewpoint, of the homogeneity and original "as-received" condition of the materials to be tested. To achieve this goal, it was decided to obtain randomized physical property data on the plastics concerned as part of a preliminary exploratory program. From such information it was hoped that it would be possible to reach a better-informed decision as to the number and distribution of test specimens to be used in the future major work; and consequently, the quantities and type of material required.

Polymethyl methacrylate was chosen as the first material to be studied in detail because it was a representative thermoplastic, was readily available in homogeneous form, and had a comparatively simple structure which could, however, be altered chemically under controlled conditions to give a variety of structural forms. The polymethyl methacrylate was supplied by two manufacturers (hereinafter referred to as A and B).

Since fairly large numbers of specimens of different shapes were to be used in the main program, uniformity as regards the material going into the various types of specimens was of prime importance, and so it was decided to machine them from cast-sheet stock. In order to obtain the requisite information just mentioned, a preliminary statistical program was designed to investigate the following variables:

1 Variation in the material supplied by manufacturers A and B to determine generally over-all differences in the material due to inherent variations, and differences in the manufacturing techniques used by A and B.

2 Variations of the material taken from different positions in a particular sheet—center, corner, center of edge, and intermediate—all with the view in mind of determining the degree of uniformity within any one sheet itself as regards positional variations.

3 Variation of the material taken from sheets of different thicknesses, $\frac{1}{4}$ in., $\frac{1}{2}$ in., and 1 in. to obtain an indication of the uniformity in the sheets as regards material cast in different sheet thicknesses.

4 Variation of material taken from the surface of the sheets, as compared with material from the center of the thicknesses, to indicate the uniformity of the material in so far as depth from the surface was concerned.

5 Variation in measured physical properties as influenced by two testing speeds, differing by ratios of approximately 10 to 1. The reason for including item (5) was twofold: (a) to get an indication of the importance of the rate of test; and (b), to have a basis of relative comparison for the importance of the first four variations. It is the results of this preliminary survey that are presented in this paper.

MATERIAL AND TEST PROCEDURE

The material investigated was supplied in duplicate by manufacturers A and B in the form of cast sheets in three thicknesses, $\frac{1}{4}$ in., $\frac{1}{2}$ in., and 1 in., and approximately 36 in. \times 36 in. in size. Manufacturer A supplied straight commercial-run stock while manufacturer B supplied material manufactured in a commercial run but under the supervision of laboratory personnel. In addition, the material supplied by B was given subsequent annealing treatments.

To facilitate that portion of the program concerned with specimen manufacture and of actual testing, it was decided to use simple bending tests throughout this preliminary work to obtain the physical data to be used in the calculations. The specimens employed were 0.2 in. thick, 0.5 in. wide, and of such length that the tests could be carried out with 3.2 in. between the supports (span-depth ratio of 16 to 1). Loads on the specimens were applied at the center of the span. The positions of the various specimens with respect to the sheets are as shown in Fig. 1.

FIG. 1 SAMPLE POSITIONS CHOSEN FROM CAST SHEETS OF POLYMETHYL METHACRYLATE

The numbered positions are diagrammatic, i.e., the group of specimens from position 3, for example, might have been taken from any of the four corners, not necessarily the one shown. Surface specimens were machined from the same surface of the sheet; interior specimens were machined from the geometric center plane of the sheets. Since the major portion of the samples to be used in the main testing program would have machined surfaces,

it was felt desirable to minimize the complication of the "skin effect;" therefore the surface specimens were loaded with the molded skin on the upper, or compression, side. The tests were conducted in an air-conditioned atmosphere of 77 F and 50 per cent relative humidity (RH) at constant rates of crosshead motion (effectively constant rates of deflection) at speeds of 0.10 and 1.00 inches per minute.

ANALYSIS PROCEDURE

The value of an experiment is measured directly by the reliability of the measurements made. Reliable measurements in turn depend upon complete, or at least adequate, recognition of the variables involved and of their relative importance. The analysis of variance assigns to each of the five previously mentioned experimental variables (and combinations of them) its appropriate share of the total experimental variation and then tests whether each such share is significantly high or merely due to chance. With the aid of the results of such an analysis, any future program can be planned with confidence. If the analysis shows a large variation, for example, due to the position from which the specimen is taken in the sheet, or due to sheet thickness, then, in future work, an effort can be made to take specimens for a given series of tests from positions close to the same spot in a given sheet, or from sheets of the same thickness. In addition to evaluating the main sources of variation, these tests give a measure of the inherent and unavoidable variation in the results to be expected due to the host of uncontrolled variables which are acting, such as slight variations in temperature, humidity, speed of test, and dimensions. This uncontrollable variation or error is used as a base value in determining the number of tests, and so the amount of material, necessary for future testing work. Details on this point will be given in a later section.

In a complete formal analysis of the five variables being considered, there are 31 categories into which the total variation would be divided. These include the five main effects of testing rate, sheet thickness, manufacturer, position in the sheet, and "depth" in the sheet, i.e., surface as compared to internal specimens. These are the most likely sources of significant variation. In addition, there are ten first-order interaction effects such as the interaction of rate and sheet thickness, manufacturer and depth, position and depth, and so forth. The variation due to an interaction term would be a variation in one factor as caused by a variation in another factor. For example, consider the interaction term "testing rate and depth." It may very well be that the total average of maximum strengths would be the same for surface specimens as for internal specimens, yet the fast surface specimens may test significantly high compared to the fast internal specimens with the slow surface specimens significantly low compared to the slow internal specimens. The magnitude of the first-order interaction term, rate and depth, would indicate this condition. In addition to the fifteen variational terms already mentioned, there are ten second-order interaction terms such as "rate \times depth \times manufacturer," and "sheet thickness \times rate \times position." Further, there are also five third-order interaction terms, and one fourth-order term. These higher-order terms are of the same nature as the first-order interactions described, but much more difficult to comprehend and to associate with a physical meaning.

CALCULATION MECHANICS

The entire following discussion will be concerned with the maximum stress values obtained from the bending tests using the formula $s = Mc/I$. A completely separate and similar analysis must be made if the modulus of elasticity values are considered.

After the tests have been completed and the data tabulated

(Table 1), the information may be entered for analysis in the form shown in Tables 2 and 3. The original maximum stress values from Table 1 have been decreased by 10,000 and divided by 10 to reduce the size of the terms to be encountered in later arithmetical manipulations. (In general, all values in the initial data may be multiplied by a constant, or have a constant added to them without affecting the results in any way.)

The entire original data have been plotted in the frequency-distribution bar graph, Fig. 2. It can be seen that the maxi-

FIG. 2 VARIANCE SERIES FREQUENCY DISTRIBUTION: MAXIMUM STRESS IN BENDING

mum bending stresses range between 9000 and 22,000 psi, and that the arithmetic mean of the stresses for materials A and B and for their total lie between 15,000 and 17,000 psi. The ordinate of this graph is calibrated in frequency units or the number of specimens which broke within the range of stresses represented along the abscissa.

Below each table the sum of values for each thickness and manufacturer is formed, and horizontally, the sum of values for each position and manufacturer is similarly obtained. This is done to facilitate construction of further tables, as will presently be appreciated. The sum of all values for a given manufacturer

may be obtained by a summation of either the horizontal or vertical sums. This latter operation provides a check on the preceding computations.

Tabulations like the ones shown in Tables 4, 5, and 6 (there would be ten such tables if all were listed, one for each of the first-order interactions) are then filled in with the appropriate sums. The totals which were formed in Tables 2 and 3 are now found to be convenient aids for making all the entries into Tables 4, 5, 6, etc., except in the case of the position versus thickness table (Table 6). Here, for example, the first entry is obtained by using the individual values in Tables 2 and 3, or $815 + 350 + 740 + 500 + 680 + 410 + 860 + 580 = 4935$. Considering now for a moment Table 4, it may be seen that the first entry is the sum of all fast-rate, "A" specimens, or 10,566 (from Table 2) + 9032 (from Table 3) = 19,598. In a similar manner the remaining three entries are obtained. As a further example, consider Table 5. The first entry is the sum of all fast-rate, position 1 specimens or 2563 + 2200 (both from Table 2) + 2079 + 2480 (both from Table 3) = 9322. This procedure is followed in filling in the remaining values.

Finally, Table 7 may be made up, putting the "sum of squares of the deviation" in the first column.

The sum of squares of deviation is defined by the series

$$\sum_{i=1}^n (\bar{x} - \bar{x})^2$$

where \bar{x} is the mean value of maximum stress considering a particular variable and \bar{x} is the mean value of maximum stress considering all of the data; n is the total number of readings or values considered. To clarify this situation a bit, take, for example, the case of the interaction "position and thickness" (see Table 6). The discussion will be simplified considerably by introducing here a few symbolisms. Let

$\Sigma x =$ total sum of all maximum stress values = 64,208

$\Sigma x_P =$ total sum of maximum stress values for any one position

= 16,156 for position 1, etc. (four values in all)

$\Sigma x_T =$ total sum of maximum stress values for any one thickness

TABLE 4 VARIANCE COMPUTING TABLE: RATE OF TEST VERSUS MANUFACTURER

Manufacturer	Fast Rate	Slow Rate	Total
A	19,598	16,842	36,440
B	15,523	12,245	27,768
Total	35,121	29,087	64,208

$$(0) \text{ Sub-total sum of squares} = \frac{1}{n_{FM}} \sum_{i=1}^n (x_{FM})^2 = \frac{1}{24} [(19,598)^2 + \dots] = 44,109,921.7$$

$$(1) \text{ Sum of squares of Rate Deviations} = \sum_{i=1}^n (\bar{x}_R - \bar{x})^2 = \frac{1}{48} [(35,121)^2 + (29,087)^2] - \frac{1}{96} (64,208)^2 = 379,262.1$$

$$(2) \text{ Sum of squares of Manufacturers Deviations} = \sum_{i=1}^n (\bar{x}_M - \bar{x})^2 = \frac{1}{48} [(36,440)^2 + (27,768)^2] - \frac{1}{96} (64,208)^2 = 783,370.7$$

$$(3) \text{ Interaction of Rate vs. Manufacturer} = \sum_{i=1}^n (\bar{x}_{FM} - \bar{x}_R - \bar{x}_M + \bar{x})^2 = 2838.3$$

TABLE 5 VARIANCE COMPUTING TABLE; POSITION VERSUS RATE OF TEST

Position	Fast Rate	Slow Rate	Total
1	9,322	6,834	16,156
2	8,474	8,073	16,547
3	8,072	6,830	14,802
4	9,253	7,450	16,703
Total	35,121	29,087	64,208

$$(0) \text{ Sub-total sum of squares} = \frac{1}{n_{PR}} \sum_i (x_{PR})^2 = \frac{1}{12} [(9,322)^2 + \dots] = 45,121,653.2$$

$$(1) \text{ Sum of squares of Rate Deviation} = \sum_i (\bar{x}_R - \bar{\bar{x}})^2 = \frac{1}{48} [(35,121)^2 + (29,087)^2] - \frac{1}{96} (64,208)^2 = 379,262.1$$

$$(2) \text{ Sum of squares of Position Deviation} = \sum_i (\bar{x}_P - \bar{\bar{x}})^2 = \frac{1}{24} [(16,156)^2 + \dots] - \frac{1}{96} (64,208)^2 = 93,422.6$$

$$(3) \text{ Interaction of Position vs. Rate} = \sum_i (\bar{x}_{PR} - \bar{x}_P - \bar{x}_R + \bar{\bar{x}})^2 = 1,704,517.9$$

TABLE 6 VARIANCE COMPUTING TABLE; POSITION VERSUS THICKNESS

Position	Original Sheet Thickness			Total
	$\frac{1}{8}$ "	$\frac{1}{4}$ "	1"	
1	4,935	6,165	5,056	16,156
2	5,150	6,490	4,907	16,547
3	4,095	5,545	5,162	14,802
4	5,280	6,185	5,238	16,703
Total	19,460	24,385	20,363	64,208

$$(0) \text{ Sub-total sum of squares} = \frac{1}{n_{PT}} \sum_i (x_{PT})^2 = \frac{1}{8} [(4,935)^2 + (5,150)^2 + (4,095)^2 + \dots] = 43,547,174.7$$

$$(1) \text{ Sum of squares of Thickness Deviation} = \sum_i (\bar{x}_T - \bar{\bar{x}})^2 = \frac{1}{n_T} \sum_i (x_T)^2 - \frac{1}{96} (\sum_i x)^2 = \frac{1}{32} [(19,460)^2 + \dots] - \frac{1}{96} (64,208)^2 = 43,374,112.3 - 42,944,450.6 = 429,661.7$$

$$(2) \text{ Sum of squares of Position Deviation} = \sum_i (\bar{x}_P - \bar{\bar{x}})^2 = \frac{1}{24} [(16,156)^2 + \dots] - \frac{1}{96} (64,208)^2 = 43,037,937.2 - 42,944,450.6 = 93,422.6$$

$$(3) \text{ Interaction of Position vs. Thickness} = \sum_i (\bar{x}_{PT} - \bar{x}_P - \bar{x}_T + \bar{\bar{x}})^2 = 79,575.8$$

TABLE 7 OVER-ALL VARIANCE ANALYSIS

Cause	Sum of Squares of Deviation	Degrees of Freedom	Mean Square Deviation	M.S.D. 3490
1) Manufacturer	783,370.7	1	783,370.7	224.46

3) Depth	109,080.2	1	109,080.2	31.26
4) Thickness	429,661.7	2	214,830.8	61.56
5) Position	93,422.6	3	31,140.9	8.92
6) Rate x Manufacturer	2,838.3	1	2,838.3	0.81
7) Depth x Manufacturer	34,504.1	1	34,504.1	0.99
8) Thickness x Manufacturer	1,645,879.8	2	822,939.9	235.80
9) Position x Manufacturer	435,061.9	3	145,020.6	41.53
10) Position x Depth	757.6	3	252.5	0.07
11) Rate x Depth	258,095.4	1	258,095.4	73.95
12) Thickness x Depth	927,902.5	2	463,951.3	132.94
13) Rate x Position	1,704,517.9	3	568,172.6	162.80
14) Thickness x Position	79,575.8	6	13,262.3	3.80
15) Thickness x Rate	91,670.0	2	45,835.0	13.13
16) 2nd 3rd 4th Order Interactions	219,868.9	63	3,490.0	1.00
17) TOTAL	7,195,535.4	95	-----	-----

= 19,460 for the $\frac{1}{4}$ in. thickness, etc. (three values in all)

Σx_{PT} = total sum of strength readings for any one combination of a specific thickness and a specific position
= 4935 for position 1, $\frac{1}{4}$ in. thickness, etc. (twelve values in all)

n_P = number of readings totaled to form each Σx_P
total number of values = 96
number of sums P = 4 = 24

n_T = number of readings totaled to form each Σx_T
total number of values = 96
number of sums T = 3 = 32

n_{PT} = number of readings totaled to form each Σx_{PT}
total number of values = 96
number of sums PT = 12 = 8

n = total number of values = 96

$i = \frac{n_T}{n_{PT}}$ = number of positions studied = 4

$j = \frac{n_P}{n_{PT}}$ = number of thicknesses studied = 3

The sum of squares of deviation between the mean maximum stress values for each thickness and the mean maximum stress for all values may now be written in the form

$$\sum_1^n (\bar{x}_T - \bar{x})^2 = \frac{1}{n_T} \sum_1^j (\Sigma x_T)^2 - \frac{1}{n} (\Sigma x)^2 \dots \dots [1]$$

The equation for computing the position deviation is analogous and of the form

$$\sum_1^n (\bar{x}_P - \bar{x})^2 = \frac{1}{n_P} \sum_1^i (\Sigma x_P)^2 - \frac{1}{n} (\Sigma x)^2 \dots \dots [2]$$

Finally, the equation for computing the deviation due to the interaction of position and thickness may be written in the form

$$\sum_1^n (\bar{x}_{PT} - \bar{x}_P - \bar{x}_T + \bar{x})^2 = \frac{1}{n_{PT}} \sum_1^i \sum_1^j (\Sigma x_{PT})^2 - \frac{1}{n_T} \sum_1^i (\Sigma x_T)^2 - \frac{1}{n_P} \sum_1^j (\Sigma x_P)^2 + \frac{1}{n} (\Sigma x)^2 \dots \dots [3]$$

Similar equations can be written for all other variables and interactions. The calculations involved in evaluating these equations numerically are shown for compactness, below each of the Tables 4, 5, 6, etc. as Equations [1], [2], and [3].

The procedure just described is followed for all entries in Table 7, including the total values, with the exception of the term consisting of the second-, third-, and fourth-order interactions. This term is equal to the total immediately below it minus all the terms above it.

The manner in which the foregoing procedure has been presented requires that the effects of the second-, third-, and fourth-order interactions be lumped together in one sum. To separate out the second-order interaction would require a duplication of about as much effort as has already been expended in making

up the present tables. A new sheet with ten additional three-way instead of two-way subtables would be required.

The degrees-of-freedom items of the second column of figures in Table 7 are obtained by subtracting one unit from the total number of items in each category. Thus, for example, because there are two manufacturers, and one of these may be "assumed," the degrees of freedom for the manufacturers is the remainder, or one. Also, since three different thicknesses of specimens were tested, and one of these may be assumed, the number of degrees of freedom is the remainder, or two, etc. Since the total number of specimens tested was 96, the total degrees of freedom is one less or 95.

The mean-square deviation, or variance, listed in the third column of Table 7, is obtained by dividing each sum of squares of deviation by its respective degrees-of-freedom value. Each of these mean-square deviations is an estimate of the variance of the 96 maximum stresses. If all 96 values were "alike," i.e., differed only at random, and had no significant trend between manufacturers, rates, thicknesses, etc., then all the estimates of variance would be alike. By alike is meant here that the values will differ from each other in magnitude, but not significantly.

Actually, from the values of the mean-square deviations shown in Table 7 we can conclude in the case of the first five causes that there was a significant difference in strength between materials A and B, since the estimate of variance due to manufacturers is significantly high. Furthermore, the estimate of variance due to position is significantly low compared to the values of the other four causes, which would indicate that there was not much difference in the maximum strength of specimens taken from various positions of the test plate or, in other words, the test plate is fairly homogeneous. It is important here to emphasize the fact that this conclusion is a relative one based upon consideration of the five primary causes, i.e., of these five causes, the position variation is the smallest. This is all that can be said at this point. The causes taken in order of importance of their influence on the maximum stress values obtained are as follows: (1) manufacturer, (2) rate of test, (3) thickness, (4) depth, (5) position.

In the case of the interaction terms, the analysis is not so simple, but here again it can be seen that the greatest influence on the maximum stress is that of cause (8), thickness versus manufacturer; and the least influence is that of cause (10) or position versus depth. The higher-order interaction terms (second, third, and fourth order in our case) do have physical meanings especially to engineers. Statisticians rarely include such in their analyses and indeed we have already obtained all the information we want so that the second and higher interactions are combined and taken as the variance or variability of the material due to such other variables not specifically considered here, such as fluctuations in temperature and humidity, and random errors in measuring dimensions, rates, deformations, etc. This variance is, so to speak, the basic, unavoidable, and unallocatable variation; and is used as the basis for comparison by which the other variances are judged significant.

The mean-square deviations which are smaller than the second-, third-, and fourth-order interactions combined obviously are not significant, but those which are considerably larger should be analyzed. To facilitate comparison, a convenient tabulation is obtained by dividing the mean-square deviation of the effect being tested by the mean-square deviation due to second-, third-, and fourth-order interactions (the lumped variation). The values obtained are shown in the last column of Table 7 and are further plotted in the form of a bar graph in Fig. 3. It is readily apparent that the general effect of manufacturer is greatly pronounced, overshadowing all else except thickness \times manufacturer, which

FIG. 3 VARIANCE SERIES COMPARATIVE VARIANCES

might conceivably also be due to the manufacturer participation. The rate of test is shown to be highly significant also, as might be expected. Thickness \times depth is certainly significant and would indicate the necessity of expecting different results from tests on specimens taken from different thicknesses at varying depths below the surface even when the tests are somewhat identical. The same is true for rate \times position.

SUBDIVIDED ANALYSIS

The over-all statistical studies here reported have grouped interaction terms which hinder specific allocation of effect to their proper factors. Thus to get a clearer idea of the relative magnitudes of the variations due to the various causes, a further, subdivided variance study has been made. Analyses of materials A and B separately to eliminate cross-terms attributable to variations between manufacturing techniques were thought most likely to clarify the situation. The computations made were carried out in the manner previously explained in detail, and have been summarized in Tables 8, 9, 10, and 11. The mean-square deviations in the last column of Tables 9 and 11 have also been plotted in the form of a bar graph in Fig. 4. Since the maximum order of magnitude was three, the analysis was carried out in detail to study the third-order effects, as shown in the tables and graphs.

Both of these subdivided analyses indicate that the largest deviation is caused by differences in physical properties of sheets of different thicknesses of apparently identical material. The remaining "mean-square-deviation" terms of the material B analysis seem to indicate that the effect of rate of loading is sizable, as normally would be expected, and, further, that positional variations and depth variations (surface versus internal

specimens) are of the same order of importance, namely, about one half the magnitude of the deviation due to rate of loading, indicating fairly homogeneous material.

In the material A analysis, it is to be noted that the deviation "between thicknesses" is very high, indicating variability in the material taken from different sheets is significant. The analysis also indicates that deviation "between positions" is also high, indicating nonuniformity over a single sheet. Further, "depth" variation is also significant, indicating a nonhomogeneous structure in material near the surface of the sheet, as compared with material near the center plane.

CONCLUSION

This variance analysis of causes and interaction terms indi-

cates that studies correlating structural characteristics of a material, whether chemical, metallurgical, etc., with its physical properties had best be done by testing samples whose homogeneity and degree of representation (reproducibility) of a material are understood and can, therefore, be taken into consideration. Further, the importance of considering interaction effects has been indicated. The latter, if not considered, can easily lead to false conclusions or effectively mask effects that may occur.

In the case of the plastic materials analyzed in the paper, it has been found that in order to eliminate as many interactions as possible, future testing should be carried out using material (for particular phases of the work) from a single manufacturer, with samples taken from panels of the same thickness, using a predetermined random sampling procedure for obtaining specimens,

Theoretical Considerations on the Optimum Adjustment of Regulators

By P. HAZEBROEK¹ AND B. L. VAN DER WAERDEN¹

In a companion paper, the authors propose some practical rules for the best possible adjustment of the parameters of automatic regulators with proportional-plus-integral action. The present paper will be concerned with the theoretical foundations of the method developed.

FUNDAMENTAL NOTIONS

IN this paper, we shall assume that a "single" variable is to be kept at a "constant" value by automatic regulation.

We begin by a short survey of the fundamental notions to be used.

Process and regulator are interconnected in such a way as to form a closed loop which we will call a "regulation circuit," Fig. 1. In a regulation circuit it is appropriate, for the purpose of our theory, to distinguish two interdependent variables as follows:

(a) The "regulated variable," which we will denote by x , which should be kept as constant as possible by suitable variations of our second variable.

(b) The "regulating flow," which we will denote by q .

We will assume that both x and q are measured from their normal value, which shall be taken as zero points and expressed in dimensionless units; for instance, as fractions of the maximum interval in which they may move.

The restriction shall be imposed that the relationship between x and q is such that the superposition principle is valid, in other words that the sum of two time-dependent disturbances of q (or x) causes a change of x (or q) which is the sum of the changes resulting from the two disturbances taken separately. This restriction has to be made in any general theory of regulation.

If the superposition principle holds good, we can confine ourselves, when studying the response of x (or q), to a "standard disturbance," i.e., a sudden deviation 1 from the normal value 0, remaining equal to 1 for all positive values of t .

We define two fundamental functions:

(a) The response function $X_R(t)$ of the "process" with respect to the considered variable x . This is the response of x to a standard disturbance of q , the circuit being open and assumed to be severed at A, between process and regulator, Fig. 1.

(b) The response function $Q_R(t)$ of the "regulator" is the response of q to a standard disturbance of x taken with a negative sign, the circuit being open and assumed to be severed at B between regulator and process.

Any time-dependent disturbance can be approximated by a succession of small "step functions" and hence can be represented by a linear combination (sum or integral) of standard disturbances. If the response corresponding to the standard dis-

FIG. 1 DIAGRAM OF REGULATION CIRCUIT

turbance 1 of q is $X_R(t)$, the response corresponding to an arbitrary disturbance $q(t)$ will be

$$\frac{d}{dt} \int_0^t q(t-\tau) X_R(\tau) d\tau \dots \dots \dots [1]$$

which operation can be conveniently represented by the symbol $q(t) \circ X_R(t)$.

In the same way we have for an arbitrary disturbance $x(t)$

$$x(t) \circ Q_R(t) = \frac{d}{dt} \int_0^t x(t-\tau) Q_R(\tau) d\tau \dots \dots \dots [2]$$

Other quantities in the regulation circuit can be derived from $X_R(t)$ and $Q_R(t)$. Especially important is the following function:

Behavior of Regulated Variable $X_B(t)$. This is the response of x to an initial standard disturbance of x under the influence of the regulator. For the sake of brevity this will often be called the behavior function.

The behavior corresponding to an arbitrary time-dependent disturbance can be found by applying a formula of the same kind as Equation [1] or Equation [2] to $X_B(t)$.

TYPES OF RESPONSE CURVES

In order to study the behavior of the variables in a regulation circuit, it is convenient to assume hypothetical response curves representing mathematical functions distinguished by simple properties. By suitable adjustment to certain parameters occurring in these functions they are adaptable to a more or less close approximation of the majority of response functions met with in practice. The latter point has been treated more fully in the practical part.

For the present we shall confine ourselves to the discussion of the kind of regulation that is performed by a regulator with proportional plus integral action, and which may be represented by the idealized response function

$$Q_R(t) = \begin{cases} 0 & \text{for } t \leq 0 \\ a + bt & \text{for } t > 0 \end{cases}$$

¹ N. V. Bataafsche Petroleum Maatschappij, The Hague, Holland. Presented at the ASME Industrial Instruments and Regulators Division - Instrument Society of America Conference at St. Louis, Mo., September 12-16, 1949.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-IIRD-1.

As for the process, two classes of response functions will be considered as follows:

1 Processes with self-regulation of the following three types;

Type A. Curves having contact of the order $n - 1$ with the axis of t

$$X_R(t) = 1 - e^{-t} \left(1 + t + \frac{t^2}{2!} + \dots + \frac{t^{n-1}}{(n-1)!} \right) \dots [3]$$

Type B. Curves with dead time T_d

$$X_R(t) = \begin{cases} 0 & \text{for } t \leq T_d \\ 1 - \exp\left(-\frac{t - T_d}{T_e}\right) & \text{for } t > T_d \end{cases} \dots [4]$$

Type C. Abrupt response with dead time T_d

$$X_R(t) = \begin{cases} 0 & \text{for } t \leq T_d \\ 1 & \text{for } t > T_d \end{cases} \dots [5]$$

Type C is a limiting case of Type A ($n \rightarrow \infty$) and also of Type B ($T_e \rightarrow \infty$).

2 Processes without self-regulation of the following two types:

Type D.

$$X_R(t) = t - n + e^{-t} \left[n + (n-1)t + \frac{n-2}{2!} t^2 + \dots + \frac{1}{(n-1)!} t^{n-1} \right] \dots [6]$$

This function is obtained from Type A by integration from 0 to t .

$$X_R(t) = \begin{cases} 0 & \text{for } t \leq T_d \\ t - T_d & \text{for } t > T_d \end{cases} \dots [7]$$

Type E is a limiting case of Type B which may be obtained from the latter by multiplying Equation [4] by T_e and letting T_e become infinite.

As we have pointed out in the practical part,² the regulation has to satisfy different requirements according to the asymptotic behavior of the disturbance. In the case of processes with self-regulation, we have taken the standard disturbance as our fundamental disturbance. In the case of processes without self-regulation, we have considered as a fundamental disturbance the time integral of the unit disturbance

$$x(t) = t \quad (t > 0)$$

The behavior of the regulated variable resulting from this disturbance will be called the "second behavior function" and denoted by $X_B^*(t)$. It is the time integral of $X_B(t)$

$$X_B^*(t) = \int_0^t X_B(\tau) d\tau$$

In all these cases the main question is: What choice of the parameters a and b of the regulator gives the best possible regulation, and between what limits can a and b vary without making the regulation much worse?

CRITERION FOR BEST REGULATION

The new feature of our theory is the putting forward of a criterion for best regulation, which has been proposed by Prof. W. J. D. van Dijk. According to this criterion we shall have optimum performance when the parameters of the response function $Q_R(t)$ (in our case a and b) are given the values for which

(1) in the case of processes with self-regulation, the integral

$$S = \int_0^\infty X_B^*{}^2 dt \dots [8]$$

² "The Optimum Adjustment of Regulators," by P. Hazebroek and B. L. van der Waerden, companion paper presented at the IIR-ISA Conference at St. Louis, Mo., Sept. 12-16, 1949.

(2) in the case of processes without self-regulation, the integral

$$S = \int_0^\infty X_B^*{}^2 dt \dots [8a]$$

attains its minimum value. This is a reasonable condition as it meets both the requirements for good regulation:

(a) The regulated variable should be quickly reduced to its normal value.

(b) The fluctuations of this variable should remain small.³

These criteria seem to be especially adapted to the special types of fundamental disturbances we have assumed. We shall prove, however, that it is also satisfactory for more general disturbances.

We will first consider processes with self-regulation.

Let X_B be the behavior of x upon a standard disturbance of x , as previously calculated. The behavior due to an arbitrary disturbance X_D is

$$x = X_D \circ X_B = \frac{d}{dt} \int_0^t X_D(t - \tau) X_B(\tau) d\tau \dots [9]$$

Now suppose that X_B becomes practically zero after a certain time T , and that X_D is a continuous, differentiable bounded function of t , which means that no sudden, but only gradually increasing and decreasing disturbances occur. In this case Equation [9] may be written

$$x(t) = \int_0^T X_D'(t - \tau) X_B(\tau) d\tau$$

Now, by a well-known inequality of Schwarz

$$\left[\int_a^b f(x)g(x) dx \right]^2 \leq \int_a^b f^2(x) dx \cdot \int_a^b g^2(x) dx$$

we have

$$x^2(t) = \int_0^T X_D'^2(t - \tau) d\tau \cdot \int_0^T X_B^2(\tau) d\tau$$

In general, we may assume that the disturbances met with in practice do not occur so suddenly and so frequently and intensely that the first factor on the right becomes extremely large. As to the second factor, we can make it as small as possible by the application of our criterion. Now if the first factor is not too large and the second one is made small, the whole product will become small, that is, the deviation $x(t)$ will be small for all values of t , which is the object of regulation. Furthermore, if during some time T no disturbances occur, $x(t)$ will be zero after this lapse of time. This is all that reasonably may be expected.

Next we turn to processes without self-regulation. If we make use of the integral, Equation [8], also for these processes, it is found that b becomes zero. When b vanishes, however, the regulated variable would not revert to its normal value when the disturbance increases linearly. As we assume that in the present case the disturbance is of the latter type, the criterion has to be modified. If we replace in our first criterion the integral, Equation [8] by [8a], and if we assume further the disturbance X_D to

³ Some readers may be inclined to think that our criterion seems somewhat artificial. It might, for instance, be argued that it would be more plausible to choose a and b in such a way that the integral of the absolute value of $X_B(\tau)$

$$S_1 = \int_0^\infty |X_B(\tau)| d\tau$$

becomes a minimum. The main objection to this is, however, that this integral is very unsuitable for mathematical treatment. Moreover, the results would in most cases not differ very much from our own.

The same argument is, at least in part, at the bottom of the method of least squares, where the sum of the squares of the deviations is minimized rather than the sum of their absolute values. In fact our method also makes a quantity with the nature of a squared error a minimum.

increase linearly for large t , the foregoing argument is again valid with some slight modifications. The proof may be left to the reader.

Thus the principle of making the integrals, Equations [8] and [8a], respectively, as small as possible for standard disturbances is justified also on the assumption of nonstandard disturbances.

The parameters a and b sometimes must be subjected to certain restrictions, e.g., that the regulated flow should never exceed a prescribed value. In this paper, however, no such restrictions are imposed, and we shall only be concerned with the integral S .

QUALITY OF REGULATION

Let S_m be the minimum of S , corresponding to the best choice of a and b . We introduce an index for the quality of regulation. The quality number N is defined as the quotient

$$N = \frac{S_m}{S}$$

The maximum value $N = 1$ corresponds to the best regulation but regulation with quality number 0.9 is nearly as good.

CALCULATION OF BEHAVIOR OF REGULATED VARIABLE AND REGULATING FLOW

In order to find S and N , it is necessary to calculate the behavior $X_R(t)$ of the variable x .

If at time $t = 0$ a standard disturbance 1 is given to x , the response of q is given by $Q_R(t)$, and the response of x to this regulating flow is given, according to Equation [1], by

$$-F_1(t) = -Q_R(t) \circ X_R(t) = -(Q_R \circ X_R)$$

Hence the regulated variable x does not remain 1, but becomes

$$1 - F_1(t)$$

But this modified disturbance gives rise to a modified response of the regulating flow

$$-(1 - F_1) \circ Q_R$$

and this in turn causes a modified response of the variable x

$$\begin{aligned} -(1 - F_1) \circ Q_R \circ X_R &= -(1 - F_1) \circ F_1 \\ &= -F_1 + (F_1 \circ F_1) \end{aligned}$$

Hence the regulated variable becomes

$$1 - F_1 + F_2; (F_2 = F_1 \circ F_1)$$

By continuation of this process we finally find the behavior of x

$$X_R = 1 - F_1 + F_2 - F_3 + \dots \quad [10]$$

where

$$F_1 = Q_R \circ X_R = \frac{d}{dt} \int_0^t Q_R(t-\tau) X_R(\tau) d\tau \quad [11]$$

$$\left. \begin{aligned} F_2 &= F_1 \circ F_1 \\ F_3 &= F_2 \circ F_1 \end{aligned} \right\} \quad [12]$$

In simple cases, for instance, in the case of a step function X_R (Type C), the Equations [10], [11], [12] can be used directly to calculate the behavior X_R . In more complicated cases, other mathematical devices to be discussed later save a considerable amount of labor.

EFFECT OF A DEAD TIME

If one of the response functions Q_R or X_R has a dead time T_d , i.e., remains zero as long as $t \leq T_d$, the same dead time will appear in F_1 , double this time in F_2 , treble in F_3 , etc. Hence for any

finite value of t only a finite number of functions F_n will be different from zero, and the series, Equation [10], has for every finite value of t only a finite number of terms, each of which can be found by direct integration if the functions X_R and Q_R are not too complicated. For large values of t the number of terms may be large, but in that case the whole sum X_R is negligibly small if regulation is at all stable and efficient.

If both functions Q_R and X_R have dead times t_1 and t_2 , the sum of these $t_1 + t_2$ will be the dead time of F_1 according to Equation [11]. It is quite irrelevant which part of this sum is due to Q_R and which to X_R ; only the sum $t_1 + t_2$ matters. A dead time in Q_R has exactly the same effect as one in X_R ; hence we can always assume that Q_R has no dead time. For any satisfactory regulator the dead time has to be very small anyway.

The simplest case for an X_R with dead time is as follows:

Response Process Type C. We can take T_d as unit of time, hence Equation [5] becomes

$$X_R = \begin{cases} 0 & \text{for } t \leq 1 \\ 1 & \text{for } t > 1 \end{cases}$$

and

$$Q_R = a + bt \text{ for } t > 0$$

Equation [11] gives

$$F_1 = Q_R \circ X_R = \begin{cases} 0 & \text{for } t \leq 1 \\ a + b(t-1) & \text{for } t > 1 \end{cases}$$

By means of Equation [12], we get

$$F_n(t) = \begin{cases} 0 & \text{for } t \leq n \\ f_n(t-n) & \text{for } t > n \end{cases}$$

the polynomials f_1, f_2, \dots being defined by the recursion formulas

$$\begin{cases} f_1 = a + bt \\ f_n = af_{n-1} + b \int_0^t f_{n-1}(\tau) d\tau = \sum_{k=0}^n \frac{n!}{(n-k)!} \frac{a^{n-k} b^k}{k!} t^k \end{cases}$$

Finally, Equation [10] gives

$$X_R(t) = 1 - f_1(t-1) + f_2(t-2) - \dots$$

The result of the calculation is shown in Fig. 2, for $a = 0.5$, and $b = 0.8$.

FIG. 2 BEHAVIOR OF REGULATED VARIABLE FOR TYPE C PROCESS

APPLICATION OF OPERATIONAL CALCULUS

In more complicated cases, when direct calculation of the series, Equation [10], is impracticable, the operational calculus is useful. The functions X_R and Q_R give rise to Laplace transforms

$$f(p) = \int_0^\infty p e^{-pt} X_R(t) dt$$

$$g(p) = \int_0^\infty p e^{-pt} Q_R(t) dt$$

The Laplace transform of the function $F_1(t) = Q_R \circ X_R$ is the product $f(p)g(p)$ and hence the transform of the series, Equation [10], is

$$\varphi(p) = \frac{1}{1 + f(p)g(p)} = \frac{F(p)}{G(p)} \dots [13]$$

In order to find the behavior function X_B , of which Equation [13] is the Laplace transform, use may be made of Heaviside's "expansion theorem," which is stated as follows:

If p_1, p_2, \dots, p_n are the roots of the equation $G(p) = 0$, each assumed to be different and none of them equal to zero, then Equation [13] is the Laplace transform of

$$X_B(t) = \frac{F(0)}{G(0)} + \sum \frac{F(p_i)}{p_i G'(p_i)} e^{p_i t}$$

The expansion theorem can be applied when $F(p)$ and $G(p)$ are polynomials, and also in the case of transcendental functions, where it becomes impracticable, however, for small values of t .

In the applications here considered, the Laplace transform of $Q_R = a + bt$ is

$$g(p) = a + \frac{b}{p} \dots [14]$$

As to $X_R(t)$, we will first consider the cases in which its Laplace transform $f(p)$ is a rational function (Types A and D). Next we shall deal with the cases in which $f(p)$ is a transcendental function (Types B, C, and E).

Formulas for S . When $f(p)$ is a rational function, the Laplace transform of $X_B(t)$ is a rational function

$$\varphi(p) = \frac{p(d_0 p^{n-1} + d_1 p^{n-2} + \dots + d_{n-1})}{p^n + c_1 p^{n-1} + \dots + c_n}$$

It is possible to find a general expression for the integral

$$S = \int_0^\infty X_B^2(t) dt$$

for any function $X_B(t)$ whose Laplace transform is a rational fraction

$$\varphi(p) = \frac{pE(p)}{(p - \alpha_1)(p - \alpha_2) \dots (p - \alpha_n)}$$

provided all the roots α_i of the denominator have negative real parts. The degree of $E(p)$ must not be higher than $n - 1$. The factor p in the numerator is necessary in order that $X_B(t)$ tends to zero for $t \rightarrow \infty$.

According to the expansion theorem, we have

$$X_B(t) = \sum_j \frac{E(\alpha_j) \exp(\alpha_j t)}{(\alpha_j - \alpha_1) \dots (\alpha_j - \alpha_{j-1})(\alpha_j - \alpha_{j+1}) \dots (\alpha_j - \alpha_n)}$$

and the value of the integral S is expressed by

$$S = - \sum_{k \neq j} \frac{E_k(\alpha_j)}{2\alpha_j \prod_{k \neq j} (\alpha_j - \alpha_k)^2} - 2 \sum_{(ij)} \frac{E(\alpha_i)E(\alpha_j)}{(\alpha_i + \alpha_j) \prod_{k \neq i} (\alpha_i - \alpha_k) \prod_{k \neq j} (\alpha_j - \alpha_k)}$$

It may be proved that S is a symmetrical function of the roots α_k , and thus can be expressed as a rational function of the coefficients c_k . Actually, S may be found more easily by means of a theorem to be stated later (Equation [15]). The general expression for S , which is rather long and complicated, is not given here but is only written down for those values of n which are of

practical interest. Also we have given the conditions of stability, according to the Hurwitz criterion

$n = 2$

$$S = \frac{d_1^2 + c_2 d_0^2}{2c_1 c_2}$$

$n = 3$

$$S = \frac{d_2^2 c_1 + (d_1^2 - 2d_0 d_2) c_3 + c_2 c_3 d_0^2}{2c_3(c_1 c_2 - c_3)}$$

Condition of stability

$$c_1 c_2 - c_3 > 0$$

$n = 4$

$$S = \frac{d_2^2(c_1 c_2 - c_3)}{2c_4(c_1 c_2 c_3 - c_3^2 - c_1^2 c_4)} + \frac{c_1(d_2^2 - 2d_1 d_3) + c_3(d_1^2 - 2d_0 d_2) + d_0^2(c_2 c_3 - c_1 c_4)}{2(c_1 c_2 c_3 - c_3^2 - c_1^2 c_4)}$$

Condition of stability

$$c_1 c_2 c_3 - c_3^2 - c_1^2 c_4 > 0$$

$n = 5$

$$S = \frac{d_4^2 \omega_0}{2c_5 G_5} + \frac{(d_3^2 - 2d_2 d_4) \omega_1 + (d_2^2 - 2d_1 d_3 + 2d_0 d_4) \omega_2 + (d_1^2 - 2d_0 d_2) \omega_3 + d_0^2 \omega_4}{2G_5}$$

$$\omega_0 = c_1 c_2 c_4 - c_3^2 - c_1^2 c_4 + c_1 c_5$$

$$\omega_1 = c_1 c_3 - c_3$$

$$\omega_2 = c_1 c_4 - c_5$$

$$\omega_3 = c_3 c_4 - c_2 c_5$$

$$\omega_4 = c_2 c_3 c_4 - c_2^2 c_5 - c_1 c_4^2 + c_4 c_5$$

$$G_5 = \omega_1 \omega_3 - \omega_2^2$$

Condition of stability

$$G_5 > 0$$

$n = 6$

$$S = \frac{d_5^2 \omega_0}{2c_6 G_6} + \frac{(d_4^2 - 2d_3 d_5) \omega_1 + (d_3^2 - 2d_2 d_4 + 2d_1 d_5) \omega_2}{2G_6} + \frac{(d_2^2 - 2d_1 d_3 + 2d_0 d_4) \omega_3 + (d_1^2 - 2d_0 d_2) \omega_4 + d_0^2 \omega_5}{2G_6}$$

$$\omega_0 = (c_2 c_4 - c_2 c_5 + c_1 c_6)(c_1 c_2 - c_3) - (c_1 c_4 - c_3)^2$$

$$\omega_1 = c_1 c_2 c_3 - c_3^2 - c_1^2 c_4 + c_1 c_5$$

$$\omega_2 = c_1 c_2 c_5 - c_2 c_5 - c_1^2 c_6$$

$$\omega_3 = c_1 c_4 c_5 - c_1 c_2 c_6 - c_3^2$$

$$\omega_4 = c_2 c_4 c_5 - c_2^2 c_6 - c_2 c_3^2 + c_1 c_4 c_6$$

$$\omega_5 = (c_2 c_3 - c_1 c_4 + c_5)(c_4 c_5 - c_3 c_6) - (c_1 c_6 - c_2 c_5)^2$$

$$G_6 = c_5 \omega_0 - c_3 c_6 \omega_1 + c_1 c_6 \omega_2$$

Conditions of stability

$$\omega_1 > 0$$

$$G_6 > 0$$

For higher values of n the expressions become too cumbersome for practical use. In some of these cases S may be found from the integral

$$S = \frac{1}{\pi} \int_0^\infty |\varphi(i\omega)|^2 \frac{d\omega}{\omega^2} \dots \dots \dots [15]$$

which follows from Parseval's theorem in the theory of the Fourier integral.

APPLICATION OF FORMULAS FOR S TO TYPES OF PROCESS A AND D.

Type A. The response of the process is given by Equation [3]. The Laplace transform is

$$f(p) = \frac{1}{(p+1)^n}$$

hence by Equations [13] and [14]

$$\varphi(p) = \frac{p(p+1)^n}{p(p+1)^n + ap + b} \dots \dots \dots [16]$$

Applying the formulas for S to the present case, Equation [16], we find, putting $a+1=k$ for $n=1$

$$S = \frac{b+1}{2bk}$$

$n=2$

$$S = \frac{bk + 2b + 2}{2b(2k-b)}$$

$n=3$

$$S = \frac{9 - k + 9b + 6bk - 3b^2}{2b(9k - k^2 - 9b)}$$

$n=4$

$$S = \frac{80 - 16k + 84b + 64bk - 66b^2 - 4bk^2 + b^2k}{2b[80k - 120b - (4k-b)^2]}$$

$n=5$

$$S = \frac{-(155b+1)x^2 + (23b^2+260b-70)x - b^3-8b^2+63b+55}{10b[-x^2-70x^3+(14b+55)x-b^2-22b]}$$

In the last case ($n=5$), we have put $k=5x$.

The values of a or k and b for which S becomes a minimum may be found by solving the equations

$$\frac{\partial S}{\partial k} = 0, \quad \frac{\partial S}{\partial b} = 0$$

It appears that there is only one set of roots of these equations which satisfies the conditions of stability.

For a table of values of a and b , we refer to the companion paper² (Table 1).

For larger values of n , the minimum of S can be found approximately by means of the integral, Equation [15].

For the case $n=4$ (third-order contact), the lines of constant N in the a, b -plane are shown in Fig. 3. It is seen that deviations of 40 per cent in a and b do not bring the quality number below 0.9. Thus a very rigorous adjustment of a and b is not necessary.

Type D (Without Self-Regulation). The method is exactly the same as in the preceding case. The Laplace transforms of the functions X_R and X_R^* are

$$f(p) = \frac{1}{p(p+1)^n}$$

$$\varphi(p) = \frac{p(p+1)^n}{p^2(p+1)^n + ap + b}$$

FIG. 3 LINES OF EQUAL QUALITY OF REGULATION FOR CASE $n=4$ OF TYPE A PROCESS

$$\left(N = \frac{S_m}{S}\right)$$

$n = 0$

$$S = \frac{1}{2ab}$$

$n = 1$

$$S = \frac{1+b}{2b(a-b)}$$

$n = 2$

$$S = \frac{2-a+4b+ab}{2b(2a-a^2-4b)}$$

$n = 3$

$$S = \frac{8-9a+27b+10ab-6b^2}{2b(8a-24b-9a^2+6ab-b^2)}$$

$n = 4$

$$S = \frac{64-112a+336b-a^3+156ab-176b^2-10a^2b+4ab^3}{2b(64a-256b-112a^2+144ab-64b^2-a^3)}$$

The values of a and b for which these expressions assume a minimum are given in Table 3 of the companion paper.²

PROCESSES OF TYPES B, C, AND E

In these cases the operational expression $\varphi(p)$ for $X_B(t)$ is transcendental and the determination of the most favorable values of a and b is far more troublesome, as the minimum value of S can only be found approximately by trial and error. For this purpose we have made use of the integral, Equation [15].

Type B. The response of the process is given by Equation [4]. Assuming $T_d = 1$, the Laplace transform of X_B is

$$f(p) = \frac{\exp(-pT_d)}{1+p}$$

hence

$$\varphi(p) = \frac{p(p+1)}{p(p+1) + (ap+b)\exp(-pT_d)}$$

In this case the integral, Equation [15], becomes

$$S = \frac{1}{\pi} \int_0^\infty \frac{(1+\omega^2)d\omega}{\omega^2(a + \cos \omega T_d - \omega \sin \omega T_d)^2 + (b - \omega \sin \omega T_d - \omega^2 \cos \omega T_d)^2}$$

In order to determine the minimum value of S , a and b have been systematically varied, and the integral has been evaluated numerically. It is only necessary to consider a finite interval from 0 to ω_0 where ω_0 must be assigned a suitable value depending upon the value of T_d . The contribution to S by the interval from ω_0 to ∞ remains nearly constant when a and b are varied, and thus does not materially affect the optimum values for a and b . It is again found that the quality of regulation remains good for a considerable latitude of variation of a and b .

The results of the calculation are recorded in Table 2 of the companion paper.²

After this somewhat more detailed exposition, we may be short about the remaining Types C and E. The best values of a and b are given in the companion paper.²

STABILITY

We conclude with a few remarks on stability of processes with dead time T_d .

When the process response has a dead time T_d the Laplace transform may be written

$$f(p) = e^{-pT_d}F(p)$$

and the Laplace transform of the behavior function $X_B(t)$ is

$$\begin{aligned} \varphi(p) &= \frac{1}{1 + e^{-pT_d}F(p) \left(a + \frac{b}{p} \right)} \\ &= \frac{p}{G(p)} \end{aligned}$$

The denominator of this function has an infinite number of roots, all of which should have negative real parts in order that regulation may be stable. Regulation becomes unstable for values of a and b for which a root crosses the imaginary axis. Moreover, b should be positive, as for negative values of b there would be a positive root.

In order to find the condition that $G(p)$ has purely imaginary roots, we substitute $p = i\omega$ and put $G(i\omega) = G_1(\omega) + iG_2(\omega) = 0$. Thus, a and b are expressed as functions of the parameter ω . These equations determine a spiral-shaped curve $\psi(a, b) = 0$ in the (a, b) -plane. The area enclosed by the smallest loop of this curve and the axis $b = 0$ is the region of stability.

As an example we consider a process of Type E with $T_d = 1$. The Laplace transform of $X_E(t)$ is in this case

$$\varphi(p) = \frac{p}{p^2 + e^{-p}(ap+b)}$$

and the limits of stability are given by the line $b = 0$, and the smallest loop of the curve

$$\begin{cases} a = \omega \sin \omega \\ b = \omega^2 \cos \omega \end{cases}$$

FIG. 4 REGION OF STABILITY FOR TYPE E PROCESS

ACKNOWLEDGMENT

Our acknowledgments are due to the N. V. de Bataafsche Petroleum Maatschappij for permission to publish this paper.

Discussion

M. D. CREECH.⁴ There are two requirements to be met in obtaining satisfactory control: One is that the amplitude of the controlled variable remain small; the other is that the amplitude approach zero at an early time. The integral of the absolute value of the amplitude gives about equal weight to the amplitude and the rapidity with which the amplitude approaches zero. As was pointed out by the authors, the integral of the square of the amplitude is more suitable to mathematical treatment. However, the integral of the square of the amplitude gives more weight to the magnitude of the amplitude and less weight to the time it takes for oscillations to die out. It now occurs to the writer that perhaps it might be better to use the integral of the fourth power or sixth power of the amplitude in certain cases.

An answer is requested to the following question: How can one tell when optimum control is obtained? Is it not possible that, in one case where the amplitude is large but quickly approaches zero and in another where the amplitude is small but takes a long time to become small, the minimum integral could be the same in both cases?

AUTHORS' CLOSURE

It may theoretically be admitted there might be some reason for the use of other than second powers in our minimum integral criterion, depending upon the relative weight of duration and amplitude of the regulated disturbance. It should however be recalled that: first, owing to several circumstances, our theory is only an approximation to any actual regulation; second, the optimum values of regulator parameters are not very critical, approximately forty per cent deviation from these values scarcely reducing the quality of regulation. For these reasons, apart

from mathematical difficulties, it seems an unnecessary refinement to consider other than second powers of amplitude, the more so as it would be difficult to decide which power should be chosen in any particular case.

The question whether our integral might have two approximately equal minimum values may be answered by the fact that in the cases we investigated, the function represented by our integral had only one single minimum, to which corresponds a definite set of values of regulation parameters. Hence in all these cases the behavior of the regulation circuit is uniquely determined. As our theory is only to be applied to regulation of processes whose response curves are sufficiently closely approximated by our hypothetical response curves, it may be expected also for these processes that optimum regulation according to our criterion is obtained for a unique set of values of regulation parameters. It may be granted that the case of two or even more minima of our integral is not a priori impossible, for example when there is more than one region of stability; it is, however, doubtful if such a case would ever be met with in practice. Anyway such a process would be beyond the scope of our theory.

At this place, reference may be made to "The Theory of Servo-Mechanisms," by James, Nichols, and Phillips, 1947, (McGraw-Hill Book Co., 1947), which came to the authors' attention after their papers had been submitted for publication. In a section of this book an approach to the control problems in many ways similar to that of the authors has been followed. The authors would like to avail themselves of this opportunity to express their thanks to Mr. N. B. Nichols of Taylor Instrument Co., firstly, for the stimulating influence of his repeatedly cited paper on "Optimum Settings for Automatic Controllers"; secondly, for discussions with members of our staff, which have resulted in considerable changes in our original design, especially of the companion paper; and thirdly, for his kindness in presenting these papers.

The Optimum Adjustment of Regulators

By P. HAZEBROEK¹ AND B. L. VAN DER WAERDEN²

In this paper a practical method is proposed for the adjustment of regulators in order to obtain the most satisfactory regulation of a process variable which should be kept at a constant value. The regulator is assumed to perform proportional and integral action, derivative action not being taken into consideration for the present.

INTRODUCTION

SO far, little attention has been paid to the problem of assigning definite values to the parameters characterizing the action of a regulator in order to obtain optimum results. However, an important paper by J. H. Ziegler and N. B. Nichols,³ has been published, which gives some simple rules and which later on will be considered more closely.

The present authors, starting from other fundamentals, have developed new conditions for the adjustment of parameters. The novel feature of their theory is the proposal of a "general criterion for best regulation." This paper, which is intended to bring their theory within the scope of practical application, can be understood independently of the underlying theoretical foundation, which will be given in a separate paper.⁴

FUNDAMENTAL NOTIONS

Before considering the subject proper the authors will recall some well-known fundamental notions to be used later.

Let x be a "regulated variable," e.g., a temperature, pressure, etc., which should be kept as constant as possible. The value of this variable is obtained by measurement. The deviation from the regulation point, i.e., from the normal value, may be identified with the displacement of the recording pen from this point, measured in arbitrary units. The regulation point will be taken as zero point and thus x is the deviation from zero.

Let q be the "regulating flow." It can be measured by the position of the final regulating element, e.g., a regulating valve, or by the air pressure regulating it, assuming a linear relationship between them. Again, the normal value assumed by q in the absence of any disturbance is taken to be $q = 0$. The sign of q is made such that positive deviations of q cause positive deviations of x .

Process and regulator constitute a closed system which will be called a "regulation circuit," Fig. 1.

The "response of the process" is defined as follows: Let the valve be given at time $t = 0$ a sudden displacement q_0 and let it be kept in this position, the valve being disconnected from the regulator. The valve movement q_0 will cause in course of time a change in the regulated variable x , which is assumed to be proportional to the valve movement q_0 . The ratio x/q_0 as a function of time is called the "process response function" and is denoted

by $X_R(t)$. Thus, in other words, we may say that $X_R(t)$ is the deviation of x due to a sudden disturbance $q_0 = 1$. This latter disturbance will be called "unit" or "standard disturbance."

It follows from this definition that the process-response curve results from the properties both of the process and of the measuring part of the regulator.

FIG. 1 DIAGRAM OF REGULATION CIRCUIT

The "response of the regulator" is defined as follows: Let the pen be given at time $t = 0$ a sudden displacement x_0 from its normal position and let the pen be kept in this position, the process being put out of circuit. The regulator will interpret the movement of the pen into a need for corrective action that is, the regulating flow $q(t)$ will become negative in order to compensate a positive x_0 . This change is assumed to be proportional to x_0 ; its opposite $-q(t)$ divided by x_0 is called the "response function of the regulator" $Q_R(t)$.

The response of a regulator with proportional plus integral action is represented by a function of the form

$$Q_R(t) = a + bt$$

From the response functions of process and regulator we may derive two functions describing the effect of regulation in the "closed" circuit. A sudden displacement x_0 of the recording pen will result in a response $x(t)$ of the regulated variable, and a response $q(t)$ of the regulating flow. The quotient $x(t)/x_0 = X_R(t)$ will be called the "behavior of the regulated variable," the quotient $-q(t)/x_0 = Q_B(t)$, the "behavior of the regulating flow."

It may happen that the theoretically best values of the regulation parameters would give rise to too violent fluctuations of the regulating flow. In this case Q_B must satisfy certain restricting conditions in consequence of which the said parameters are not allowed to exceed certain limiting values. These conditions depend upon the nature of the particular plant under consideration. As it is difficult to give satisfactory general rules, this point is merely mentioned here but henceforth will be left out of account.

CLASSIFICATION OF PROCESSES

By considering the process-response functions we can distinguish two classes of processes:

- 1 Those processes in which the regulated variable tends to a

³ "Theoretical Considerations on the Optimum Adjustment of Regulators," by P. Hazebroek and B. L. van der Waerden, companion paper being presented at the present IIRD-ISA Meeting.

Presented at the ASME Industrial Instrument and Regulators Division-Instrument Society of America Conference, St. Louis, Mo., September 12-16, 1949.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-IIRD-2.

new fixed value, when a standard disturbance is applied to the regulating flow (processes "with" self-regulation).

2 Those processes in which the regulated variable increases or decreases indefinitely with time under the influence of a standard disturbance in the regulating flow (processes "without" self-regulation). We will consider especially the important case in which the increase is linear after a certain lapse of time.

TYPES OF DISTURBANCES

When defining the behavior functions as mentioned, a standard disturbance x_0 is assumed to be given to the regulated variable. In practice, however, the disturbances occurring in a process usually do not originate in the measuring part of the circuit, but may be introduced at any point in the process part. Hence the disturbance in the regulated variable in most cases is not a standard disturbance, but responds to some transformation of the initial disturbance somewhere else in the process.

We will distinguish the disturbances occurring in the regulated variable according to their asymptotic behavior for large values of t :

- 1 The disturbance tends to zero after a certain lapse of time.
- 2 The disturbance tends asymptotically to a fixed value. The simplest disturbance of this kind is the standard disturbance, introduced previously.
- 3 The disturbance increases indefinitely with time.

POSSIBLE COMBINATION OF PROCESSES AND DISTURBANCES

Each of the disturbances just classified may occur in each of the two classes of processes previously mentioned.

As the type of regulator to be chosen and its adjustment for optimum regulation depend on which of these cases we are considering, all these cases should be discussed from a theoretical point of view. In practice, however, two of the theoretically possible combinations are especially important: We will confine ourselves in this paper to these cases, which are as follows:

1 Processes with self-regulation, when a disturbance of the second kind is applied to the regulated variable. As will be shown later, it is sufficient for our purpose to consider the standard disturbance.

2 Processes without self-regulation whose response functions increase linearly with time, when a disturbance $x = t$ is applied to the regulated variable (special case of third kind of disturbance). An example is the regulation of a liquid level. The disturbance then usually results from a sudden change of the regulating flow, which is transformed into a linearly increasing disturbance of the regulated variable.

In this second case the behavior function $X_B(t)$, corresponding to a standard disturbance in the regulated variable, has mainly a theoretical significance. The response to a disturbance

$$x(t) = \begin{cases} 0 & \text{for } t < 0 \\ t & \text{for } t > 0 \end{cases}$$

(time integral of a standard disturbance) is far more important for judgment of the behavior of the regulated variable. This response function, which we shall call the "second behavior function" $X_B^*(t)$, is the time integral of $X_B(t)$

$$X_B^*(t) = \int_0^t X_B(\tau) d\tau$$

CONSTANTS OF REGULATOR

Two constants characterize the response function of the type

of regulator we are discussing: the sensitivity⁴ of proportional response and the "reset rate" b/a .

Sensitivity is concerned only with the first (vertical) part of the response curve; it is valve movement per pen movement. In practice it is customary to use in place of sensitivity the proportional band, defined as

$$PR = \frac{1}{a} \cdot \frac{q_m}{x_m} \cdot 100$$

where

q_m = maximum interval of the regulating flow

x_m = scale interval of the regulated variable

The reset rate is concerned with the second part of the curve; it is the number of times per unit of time that automatic reset repeats the proportional response a . Hence the reset rate b/a has the dimension of an inverse time; in fact, the reciprocal a/b , the reset time T , is the time in which proportional response is repeated, see Fig. 2.

FIG. 2 RESPONSE CURVE OF REGULATOR OF PROPORTIONAL-PLUS-INTEGRATING TYPE

CRITERION FOR BEST REGULATION

Regulators with proportional plus integral action allow an adjustment of the parameters a and b/a within relatively wide limits. Hence the question arises: Which values of a and b/a will give the best regulation, reducing any disturbance of x to zero within a short time, without giving rise to violent fluctuations?

Before it is possible to answer this question, it should first be decided what we are to consider as the best possible regulation. The authors have adopted the following criterion, the justification of which they have given in their theoretical paper:³

1 For processes with self-regulation, optimum regulation will be obtained for those values of the parameters a and b for which the time integral of the square of the behavior of the regulated variable

$$S = \int_0^{\infty} X_B^2 dt$$

attains its minimum value.

2 For processes without self-regulation, the time integral of the square of the second behavior function

$$S = \int_0^{\infty} X_B^{*2} dt$$

should be minimized.

We have applied this criterion to a number of hypothetical process-response curves representing mathematical functions with particularly simple properties. For the details of the calculations we refer to our theoretical paper.³ These curves, to-

⁴ Sometimes sensitivity is identified with proportional band, which seems to us a confusing practice.

gether with the values of a and b , corresponding to optimum regulation, are given in Table 1.

50	0.516	0.0162

Processes With Self-Regulation:

Type A

$$X_R(t) = 1 - e^{-t} \left(1 + t + \frac{t^2}{2!} + \dots + \frac{t^{n-1}}{(n-1)!} \right)$$

(Fig. 3 for $n = 4$)

FIG. 3 RESPONSE CURVE OF TYPE A PROCESS

Type B

$$X_R(t) = \begin{cases} 0 & \text{for } t < T_d \\ 1 - \exp\left(-\frac{t - T_d}{T_e}\right) & \text{for } t > T_d \end{cases} \quad (\text{Fig. 4})$$

FIG. 4 RESPONSE CURVE OF TYPE B PROCESS

For time lag $T_d = 1$, we find approximately for different values of the time constant, data in Table 2.

TABLE 2

$\frac{1}{T_e}$	a	b
0.2	4.0	0.53
0.3	2.77	0.54
0.5	1.79	0.55
0.7	1.37	0.56
1	1.07	0.57
1.5	0.84	0.60
2	0.73	0.62
3	0.63	0.66
5	0.55	0.68
∞	0.50	0.80

Type C. Abrupt response with dead time T_d

$$X_R(t) = \begin{cases} 0 & \text{for } t < T_d \\ 1 & \text{for } t > T_d \end{cases} \quad (\text{Fig. 5})$$

FIG. 5 RESPONSE CURVE OF TYPE C PROCESS

This is a limiting case of Type A when n becomes infinite and the time scale is transformed into $t' = T_d t/n$. It is also a limiting case of Type B when T_e becomes infinite. The most favorable values of a and b are

$$a = 0.50, \quad b = \frac{0.8}{T_d}$$

Processes Without Self-Regulation:

Type D

$$X_R(t) = t - n + e^{-t} \left(n + (n-1)t + \frac{n-2}{n!} t^2 + \dots + \frac{1}{(n-1)!} t^{n-1} \right)$$

(Fig. 6 for $n = 5$)

FIG. 6 RESPONSE CURVE OF TYPE D PROCESS

Best values of a and b are given in Table 3.

TABLE 3

n	a	b
0 and 1	∞	∞
2	1.211	0.0917
3	0.571	0.0335
4	0.375	0.0174

Type E

$$X_R(t) = \begin{cases} 0 & \text{for } t < T_d \\ t - T_d & \text{for } t > T_d \end{cases} \quad (\text{Fig. 7})$$

Best values of a and b

$$a = \frac{1.11}{T_d}, \quad b = \frac{0.24}{T_d^2}$$

Type E may be obtained as a limiting case of Type D for $n \rightarrow \infty$ after having reduced both the time scale and the scale of the regulated variable by a factor T_d/n .

CHARACTERISTIC PARAMETERS OF PROCESS RESPONSE CURVES INTRODUCED BY ZIEGLER AND NICHOLS

In order to apply these theoretical results to the response curves produced by actual processes, it is necessary to define

FIG. 7 RESPONSE CURVE OF TYPE E PROCESS

certain quantities which determine to a more or less close approximation the shape of the response curve. In this we follow the same lines as Ziegler and Nichols.

Ziegler and Nichols introduce two parameters occurring in a process-response curve (see Fig. 8)

R_1 = maximum slope of curve = time derivative in point of inflection⁵

L = time lag: distance along the axis from origin to point of intersection with inflection tangent.

FIG. 8 CHARACTERISTIC PARAMETERS OF PROCESS-RESPONSE CURVE ACCORDING TO ZIEGLER AND NICHOLS

The parameters a and b/a of the regulator are now to be expressed in the introduced process parameters, in order to adapt the response curve of the regulator to the process-response curve.

Whereas L has the dimension of a time, the dimension of R_1L is "pen movement per valve movement." The inverse values $1/L$ and $1/(R_1L)$ have just the dimensions required for the reset rate and the sensitivity of a regulator. Hence Ziegler and Nichols define the optimum values of a and b/a by the formulas

$$\text{Sensitivity } a = \frac{0.9}{R_1L} \quad [1]$$

$$\text{Reset rate } \frac{b}{a} = \frac{0.3}{L} \quad [2]$$

The factors 0.9 and 0.3 are based on data obtained from practical experience.

COMPARISON OF ZIEGLER AND NICHOLS' RESULTS WITH PRESENT AUTHORS' RESULTS

We have applied Ziegler and Nichols' rules to a set of our response curves Type B. Each of the curves is characterized by its "time constant" T_e .

⁵ Ziegler and Nichols first introduce a quantity $R = \max \frac{dx}{dt}$ for arbitrary q_0 , but afterward they divide it by q_0 , and thus obtain the "unit reaction rate" R_1 .

Taking T_d as time unit, the values to be substituted in the formulas of Ziegler and Nichols are

$$\left. \begin{aligned} L &= T_d = 1 \\ LR_1 &= T_d \cdot \frac{1}{T_e} = \frac{1}{T_e} \end{aligned} \right\} \quad [3]$$

Hence the optimum sensitivity and reset rate would be, according to those authors

$$a = \frac{0.9}{LR_1} = 0.9 T_e \quad [4]$$

$$\frac{b}{a} = \frac{0.3}{L} = 0.3 \quad [5]$$

For comparison, the authors' results and those of Ziegler and Nichols are recorded side by side in Table 4.

TABLE 4 COMPARISON OF AUTHORS' RESULTS AND THOSE OF ZIEGLER AND NICHOLS

$\frac{1}{T_e}$	—Authors' results—		—Ziegler and Nichols' results—		
	a	$\frac{b}{a}$	a	$\frac{b}{a}$	
0.2	4.0	0.13	4.5	0.3	Reset rate high
0.3	2.77	0.195	3.00	0.3	
0.5	1.79	0.31	1.80	0.3	
0.7	1.37	0.41	1.28	0.3	
1.0	1.07	0.53	0.90	0.3	Good agreement
1.5	0.84	0.71	0.60	0.3	
2.0	0.73	0.85	0.45	0.3	Reset rate low
3.0	0.63	1.05	0.30	0.3	
5.0	0.55	1.24	0.18	0.3	Reset rate and sensitivity low
∞	0.50	1.38	0	0.3	

We have found that in all the cases we have computed, the minimum for S is very flat, so that for considerable deviations of a and b from their optimum values regulation still remains satisfactory. In our theoretical paper,³ we have given an instance where, even with deviations of 40 per cent, regulation remains good and, in other cases we have investigated, the conditions were found to be quite similar. Taking this into account, it may be stated that for $T_d < T_e$ (except when T_d/T_e is very small) the values of a and b found by both methods agree very well. For larger T_d/T_e , however, the reset rate given by Ziegler and Nichols' rule is far too low, and so is the sensitivity a for still larger T_d/T_e .

This conclusion is in accordance with a statement of Ziegler and Nichols in a later paper:⁴ "These settings appear to be very nearly correct on the processes tested for wide variations of R and L . On those infrequent processes in which L becomes greater than Z , Fig. 2,⁷ the settings given are too conservative."

Now L is our T_d and Z is our T_e , hence the "infrequent processes" to which Ziegler and Nichols' rules are admittedly not applicable are just the cases with $T_d/T_e > 1$. The cases with small lags ($T_d < T_e$) are those in which regulation is easy, whereas great lags make it difficult. As we shall see, it is possible to modify the rules of Ziegler and Nichols in such a way that they become generally applicable also in cases where the time lag is large.

MODIFICATION AND EXTENSION OF CONCEPTS INTRODUCED BY ZIEGLER AND NICHOLS

Ziegler and Nichols' formulas cannot be improved as long as only the constants L and R_1 , lag and slope of the process-response curve, are taken into account. Hence in order to give rules with

⁴ "Process Lags in Automatic-Control Circuits," by J. G. Ziegler and N. P. Nichols, Trans. ASME, vol. 65, 1943, p. 435.

⁷ Compare Fig. 9 of this paper where $L_2 = Z$.

a wider range of application, a third constant must be introduced. We can choose for this constant, in the case of processes with self-regulation in which x tends to a finite ultimate value, either the "height" H , of the horizontal asymptote or the "second lag" L_2 , described by Ziegler and Nichols as the time difference between the points of intersection of the inflection tangent with the t -axis and the asymptote (Fig. 9). H and L_2 are connected by the relation

$$H = R_1 L_2$$

For processes without self-regulation, H and L_2 are both ∞ .

FIG. 9 EXTENDED DEFINITION OF CHARACTERISTIC PARAMETERS OF PROCESS-RESPONSE CURVE

Owing to the difference in definition of the criterion for best regulation, processes with and without self-regulation must be treated separately.

PROCESSES WITH SELF-REGULATION

The second lag L_2 has, like L , the dimension of a time. Hence the lag quotient

$$\lambda = \frac{L}{L_2} = \frac{R_1 L}{H} = \frac{K}{H} \quad [6]$$

is a dimensionless quantity. The product $R_1 L$ has a simple geometrical meaning; it is the "distance" K , measured from the origin down to the inflection tangent.

We now replace Equations [1] and [2] by the more general ones

$$\text{Sensitivity } a = \frac{\alpha}{R_1 L} = \frac{\alpha}{K} \quad [7]$$

$$\text{Reset rate } \frac{b}{a} = \frac{\beta}{L} \quad [8]$$

where the dimensionless quantities α and β are functions of λ , and are assigned such values that for curves Type B the Equations [7], [8] yield the exact optimum values of Table 2. For these curves the lag quotient is

$$\lambda = \frac{T_d}{T_c}$$

and since a , b , R_1 , and L are known in each of the ten cases, the coefficients α and β can be calculated from Equations [7] and [8], with the results given in Table 5.

For $\lambda < 0.2$

$$\alpha = 0.74 + 0.3\lambda, \quad \beta = 0.7\lambda$$

The case $\lambda = 0$ requires some comments. It will be seen from Equation [6] that λ may become zero in different ways, as follows:

TABLE 5 OPTIMUM VALUES OF a AND b FOR TYPE B RESPONSE

λ	α	β
0.2	0.80	0.14
0.3	0.83	0.20
0.5	0.89	0.31
0.7	0.96	0.41
1.0	1.07	0.54
1.5	1.26	0.71
2.0	1.46	0.85
3.0	1.89	1.05
5.0	2.75	1.23
∞	∞	1.60

1 When L becomes zero, which corresponds to a process with self-regulation and with dead time = 0.

2 When H becomes infinite, corresponding to a process without self-regulation and having a dead time different from zero.

Only the first possibility is of interest. We have seen that for processes without self-regulation our criterion for best regulation should be modified, so that the values for $\lambda = 0$, $\alpha = 0.74$, $\beta = 0$ are of no use for this second case.

TEST OF IMPROVED FORMULAS

In order to test whether Equations [7], [8] are also applicable to other process-response curves than those of Type B, for which they have been derived, we have applied them to Type A curves without dead time.

The optimum values of a and b have been given in Table 1 and the corresponding values of λ , α , and β , which can be found analytically, are recorded in Table 6.

TABLE 6 OPTIMUM VALUES FOR TYPE A RESPONSE

n	λ	α	β
3	0.218	0.600	0.146
4	0.319	0.523	0.265
5	0.410	0.526	0.366
10	0.773	0.535	0.774
25	1.500	0.832	1.10
50	2.326	1.200	1.28

For comparison, the values of α and β for both Type A and Type B response are represented graphically in Figs. 10 and 11. For small values of λ , comparison is impossible, because in the case of the A-curves for $n < 3$, a and b become infinite. For

FIG. 10 CURVES REPRESENTING α AS A FUNCTION OF λ

FIG. 11 CURVES REPRESENTING β AS A FUNCTION OF λ

small λ the best values of α and β depend very much upon the shape of the response curve near the origin. For these cases our theory would not be of interest anyway, as the values of our parameters become so high that on-and-off regulation would be the most favorable type of regulation that could be realized practically.

FINAL CHOICE OF α AND β

In view of the fact that a considerable deviation from the best values of the regulator parameters does not affect the quality of our regulation materially, the agreement of the α and β curves of both types may be considered fairly satisfactory. The response curves encountered in practice will have, roughly, the same shape as the curves of Types A and B. For any observed curve H , L , and L_2 or R_1 can be measured and thus λ is known. The corresponding optimum values of α and β will be somewhere near the values obtained for the Type A and B response curves. Owing to the relatively wide latitude of variation allowed for α and β we may assume universal values which we select somewhere intermediately between the two sets already found. These finally recommended values are recorded in Table 7 (for graphical representation see Figs. 10 and 11).

TABLE 7 SELECTED UNIVERSAL VALUES OF λ , α , AND β

λ	α	β	λ	α	β	λ	α	β
...	1.0	0.87	0.62	2.0	1.20	1.00
...	1.1	0.90	0.67	2.2	1.28	1.05
0.2	0.68	0.14	1.2	0.93	0.71	2.4	1.36	1.10
0.3	0.70	0.21	1.3	0.96	0.76	2.6	1.45	1.14
0.4	0.72	0.27	1.4	0.99	0.80	2.8	1.53	1.17
0.5	0.74	0.33	1.5	1.02	0.84	3.0	1.62	1.20
0.6	0.76	0.40	1.6	1.06	0.88	3.2	1.71	1.23
0.7	0.79	0.46	1.7	1.09	0.91	3.4	1.81	1.25
0.8	0.81	0.52	1.8	1.13	0.94	3.6	1.90	1.27
0.9	0.84	0.57	1.9	1.17	0.97	3.8	2.00	1.28
1.0	0.87	0.62	2.0	1.20	1.00	4.0	2.10	1.30

For $\lambda > 3.5$ the following formulas may be used

$$\left. \begin{aligned} \alpha &= 0.5\lambda + 0.1 \\ \beta &= 1.6 - \frac{1.2}{\lambda} \end{aligned} \right\} \dots \dots \dots [9]$$

It should be observed that these values of α and β should be used only for process-response curves of more or less "normal" shape. In exceptional cases one may meet with process-response curves which differ considerably from the hypothetical curves of Types A and B. For these cases the best values of the regulation parameters should be determined by separate investigation.

PRACTICAL RULES

Summarizing, we have the following practical rule: Find L , K , and H as indicated in Fig. 9, from the response curve of the process to a sudden increase q_0 of the regulating flow; calculate the lag quotient

$$\lambda = \frac{K}{H}$$

find α and β from Table 7, and take

$$\text{Sensitivity } a = \frac{\alpha}{K}$$

$$\text{Reset rate} = \frac{b}{a} = \beta/L$$

From the sensitivity, the proportional band (PB) may be computed easily.

$$\text{PB} = \frac{1}{a} \cdot \frac{q_m}{x_m} \cdot 100$$

where

$$\begin{aligned} q_m &= \text{maximum interval of regulating flow} \\ x_m &= \text{scale interval of regulated variable} \end{aligned}$$

The values of H , K , L , α , and β need be known only with an accuracy of, say, 10 per cent, because even a much greater variation in the adopted values of a and b does not make regulation materially worse.

It will be seen that the numerical values of the factors a , K , and H depend on the units of the variables q and x , whereas the b -values depend on the unit of time.

PROCESSES WITHOUT SELF-REGULATION

For processes without self-regulation the parameter λ becomes zero, and the parameters α and β may be defined in the same way as before by Equations [7] and [8]. The values of α and β calculated from the data for Types D (Table 3) and E are given in Table 8.

TABLE 8 VALUES OF α AND β CALCULATED FROM DATA FOR TYPES D AND E

λ	α	β
2	2.42	0.151
3	1.71	0.176
4	1.50	0.186
∞	1.11	0.22

Table 8 shows that there may be a considerable variation of the best values of a and b for different response curves possessing the same values of K and L . If we take as a reasonable compromise $\alpha = 1.5$, $\beta = 0.18$, we have the following practical rule for processes without self-regulation:

Find L and K from the response curve of the process and take

$$\left. \begin{aligned} \text{Sensitivity } a &= \frac{1.5}{K} \\ \text{Reset rate } \frac{b}{a} &= \frac{0.18}{L} \end{aligned} \right\} \dots \dots \dots [10]$$

Furthermore, the same observations which have been made with respect to processes with self-regulation apply here also.

Finally, we wish to stress the following points:

1 Our theory starts from idealized assumptions, viz., the validity of the superposition principle both for process and regulator, and ideal proportional and integral action of the regulator. Either of these assumptions is only realized to a rather rough approximation.

2 When testing our theory on actual processes this should be done with respect to our criterion of minimizing the integral S . It goes without saying that the adoption of any other criterion leads to other optimum values of a and b .

ACKNOWLEDGMENT

Our acknowledgments are due to the Management of the N. V. de Bataafsch Petroleum Maatschappij (Royal Dutch/Shell Group) for its kind permission to publish this paper. We would also mention Messrs J. van der Veen, F. C. L. van Vugt, and E. Wieringa of this company, whose comments and criticisms have had considerable influence on the final shaping of this paper, and Mr. H. J. Krajenbrink, who carried out most of the computations.

The Exhaust-Heated Gas-Turbine Cycle

By D. L. MORDELL,¹ MONTREAL, CANADA

The author describes and discusses a gas-turbine cycle in which the combustion chamber is placed behind the turbine, raising the exhaust temperature to a level at which all the heat required for the compressor air can be supplied by the heat exchanger. The possibilities of such a cycle for the utilization of low-grade solid or liquid fuels are explained and attention is drawn to the convenience with which steam can be generated from the otherwise wasted heat, and the over-all thermal efficiencies which may be obtained by a combination of gas and steam turbines.

INTRODUCTION

IN the past decade a great deal of experimental work has been done on the gas turbine, and much has been published on the subject. Surveying the present position, the advantages of the gas turbine, for fields other than aircraft propulsion, appear to be its compactness, low cost, and ease of control. With present metallurgical and aerodynamic limitations the simple "open cycle," with no allowances for auxiliaries, can achieve thermal efficiencies of the order 25 per cent, or, by the use of heat-exchange apparatus, 30 per cent. To improve compactness and specific weight, and to obtain a flat efficiency-load curve, resort may be had to compounding, intercooling, and reheating, which also will improve the thermal efficiency.

Criticisms which may be leveled at open-cycle gas turbines are that compared with a steam plant the efficiency is about the same, but the gas turbine demands more expensive fuels, as it is difficult to burn coal; and that, compared with the Diesel engine, although it can burn cheaper fuel, the gas turbine cannot yet approach the best efficiency of the Diesel.

By employing a closed cycle, the gas turbine can be made more compact and able to burn a wide range of fuels, including coal, but the engine becomes much more complex. There is no marked effect on thermal efficiency, which, as in the open cycle, depends on temperature, component efficiencies, and cycle layout.

It is the purpose of this paper to discuss a simple cycle in which solid and other low-grade fuels can be burned with a thermal efficiency of the order 20-25 per cent, excluding auxiliaries, and further to show how this may be brought up to nearly 40 per cent without departing from solid-fuel combustion, and without increasing the complexity of the plant unduly.

THE EXHAUST-HEATED CYCLE

The objection to burning solid fuels, and also certain low-grade liquid fuels, in an open-cycle gas turbine, lies in the difficulty of separating completely the ash from the combustion products. Ash passing through the turbine blades has a powerful erosive effect, while the accidental passage of any large pieces would be catastrophic. Furthermore, the deposition of solid matter on the blades has a deleterious aerodynamic effect that will demand frequent cleaning, necessitating opening the turbine. Residual fuel

oils also may contain metallic salts which, after oxidation, may condense on the turbine blades, with serious effects.

In the closed cycle, the compressed air is heated in a form of air heater, so that the working fluid is quite distinct from the combustion gases. The fluid passing through the turbine is pure air, while any deposition of solid matter from the combustion gases is confined to stationary heat-transfer surfaces, from which it may be removed easily, if necessary, even while the plant is running.

In what the author terms the exhaust-heated cycle, the air used for combustion is that rejected from the turbine, and heating of the air prior to entering the turbine is accomplished entirely by a heat exchanger. This is illustrated diagrammatically in Fig. 1. No detailed discussion of this type of cycle has been

FIG. 1 DIAGRAM OF THE EXHAUST-HEATED GAS-TURBINE CYCLE

found by the author in the published literature, although the principle is disclosed in patents of Haverstick² and Lysholm.³

It is evident that in such a cycle, compared with a conventional open cycle operating at the same compression ratio, turbine temperature, component efficiencies, and so forth, the transposition of the combustion chamber will not affect the specific power output (power developed per pound of air circulating per second), and, if the exchanger had 100 per cent effectiveness or thermal ratio, would not alter the thermal efficiency. For any thermal ratio less than 100 per cent, however, the final discharge temperature obviously will be higher than in the open cycle, leading to a reduction in thermal efficiency.

CYCLE PERFORMANCE

In calculating cycle performance, the basic assumptions made are as follows: Compressor efficiency, 85 per cent; turbine efficiency, 87 per cent; system pressure losses, 10 per cent; combustion efficiency, 100 per cent.

It is appreciated that these figures may be considered optimistic or conservative, depending upon the particular circumstances, but it was felt that they represent a reasonable basis for a general survey, while any particular value for the combustion efficiency simply multiplies the thermal efficiency.

Fig. 2 shows values of thermal efficiency and specific power for various values of the heat-exchanger thermal ratio for an assumed turbine-entry temperature of 1300 F. It is at once evident that thermal ratios of the order 0.75 are necessary for reasonable efficiencies, and the accompanying curves are based on this value.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-F-6.

Fig. 3 shows the effect of turbine-entry temperature upon the performance. When using a heat exchanger, intercooling is usually beneficial, and Fig. 4 shows the effect of using an intercooler and a two-stage compressor. One stage of intercooling was assumed, placed so as to give equal temperature rises in each stage of the compressor. The improvement both in thermal efficiency and in specific power is quite considerable, and to complete the picture Fig. 5 shows the effect of reheating. This is accomplished as the air passes from the compressor turbine to the power turbine. Table 1 compares significant results. In each case we have assumed a heat exchanger of 0.75 thermal ratio and 1400 F turbine temperature.

The use of cooled blades in the turbine, permitting much higher gas temperatures, has not been presented at this stage. The benefits to specific output and efficiency are of course considerable, but their use is not considered practical in the immediate future because of the heat-exchanger tubes. For example, at 10 to 1 compression ratio, and turbine-entry temperature 2040 F, the specific output is 163 bhp per lb per sec, and the thermal efficiency 29.8 per cent, but the combustion temperature

Exhaust heat + intercooler + reheat	108	28.5	127	30

required would be 2500 F, with metal temperatures at the hot end of the exchanger tubes of 2240 F.

CYCLE PERFORMANCE WITH EXHAUST STEAM GENERATION

The exhaust-heated cycle lends itself peculiarly well to the production of steam. The fact that exhaust temperatures are

higher, and that the heat exchanger is at the exhaust end of the cycle means that it is only necessary to include extra transfer surface past which the exhaust will flow after heating the compressed air. The steam may be used as process steam, for district heating, or in a turbine coupled to the gas-turbine shaft. Aspects and estimates of the waste-heat boiler were recently discussed by Fusner.⁴ The limitation on steam production is twofold. First we must not cool the exhaust below its dew point. This, however, owing to the large amount of excess air in the combustion chamber, will be in the region of 250 F, compared with the usual safe minimum temperature of 350–400 F used in boiler practice. The second factor is that in the production of the steam, a large fraction of the heat must be put in at, or above the saturation temperature, and this limits the amount of heat which can be extracted from the air by further cooling below the saturation temperature. Fusner based his estimates on the assumption that the air is cooled only down to the saturation temperature of the steam, so that his figures are somewhat conservative.

In Fig. 6 are shown the percentage heat transfer possible at various steam pressures and exhaust-gas temperatures, both for

FIG. 6 FRACTIONAL HEAT RECOVERY IN A WASTE-HEAT BOILER

saturated and superheated steam. It should be emphasized that no account has been taken of dew-point considerations. The curves represent the thermodynamic limitations on heat transfer. The efficiency with which the steam is used also must be considered, and in Fig. 7 are shown the final results of using the steam produced by the waste-heat boiler in a steam turbine of 85 per cent efficiency and with a condenser pressure of 0.5 psi.

If we consider an exhaust-heated engine of compression ratio 4.5 to 1, with turbine-entry temperature of 1400 F, the thermal efficiency is 21.6 per cent. The exhaust temperature is just about 850 F. With this, using superheated steam, to avoid excessive moisture, we could recover 0.215×0.784 of the initial heat supply, or 16.8 per cent, giving an over-all efficiency of 38.4 per cent. The condenser and feedwater pump power demands probably would reduce this to about 36 per cent.

THE EXHAUST-HEATED CYCLE IN PRACTICE

So far we have considered only the thermodynamic aspects of exhaust heating. Summing up, exhaust heating gives a performance identical in specific output, and having about 75 per cent of the thermal efficiency of the conventional open cycle with heat exchanger. Let us now discuss the more practical aspects.

Combustion. The essential differences in the combustion chamber are that combustion is at an elevated temperature, prac-

FIG. 7 EXHAUST-HEAT UTILIZATION IN A STEAM TURBINE

tically atmospheric pressure, and the combustion products have to pass only through the heat exchanger. Thus we may expect a larger combustion chamber due to the lower pressure, but at the same time it is no longer a pressure vessel, permitting simplification in its construction. It is essentially a firebox similar to those in boilers, and as such, should be capable of burning any fuel that is ordinarily burned as boiler fuel. The elevated air temperature will assist materially in handling low-grade and high-moisture fuels. Since it is at almost atmospheric pressure, and could be at subatmospheric pressure were an induced-draft fan used to overcome the pressure loss in the heat exchanger, firing arrangements can be simple. One can envisage a hand-fired gas turbine without much trouble!

If a conventional mechanical stoker is used to burn coal, the undergrate air could not conveniently be taken from the main air stream owing to its high temperature, but it is a simple matter to provide a fan, which need be of very small power ($1/2$ to 1 per cent of the net output) to supply cool air under the grates. By the use of a suitable stoker and firebox design it would be possible to burn coal or oil indiscriminately.

The Heat Exchanger. The exchanger obviously is going to require 3 or 4 times the heating surface of the conventional exchanger, in addition to running at a higher mean temperature. A high thermal ratio is essential. There is one factor, however, which enables a given thermal ratio to be obtained by less surface area relative to its duty than would be required for the exchanger of a conventional cycle. Since we are heating the air immediately prior to its entry to the heat exchanger by an amount which will necessitate air-fuel ratios considerably greater than stoichiometric, we would normally separate the air for combustion and subsequent dilution. However, in the exhaust-heated cycle there is no need to obtain a uniform stream of gas for a turbine, and we conveniently may retain the separation, using the hot gases resulting from nearly stoichiometric combustion, for a second pass of the heat exchanger, the first pass being heated by the "dilution" air, which of course is already at a fairly high temperature.

The optimum choice of design here to obtain the smallest heat exchanger is complex and requires further analysis, but offers a prospect of a small saving in weight and bulk.

Cleaning of the heat-exchanger surfaces can be accomplished by soot blowers, while the engine is running, while ash or slag removal can follow normal practice.

Control. If a liquid or pulverized solid fuel is being burned, the power output of the engine may be controlled easily by altering the fuel-supply rate. If solid fuel is being burned on a grate, the simplest control would be, in effect, to by-pass the air from

⁴ "The Gas Turbine With a Waste-Heat Boiler," by G. R. Fusner, *Mechanical Engineering*, vol. 70, 1948, pp. 515–518.

the firebox. This would lower the turbine-inlet temperature quite rapidly, depending upon the thermal capacity of the exchanger, while the hot fuel bed on the grate would remain, for quite a long time, at a temperature high enough to respond immediately as soon as air was readmitted under the grates.

For starting up, on solid fuel, a supply of air under the grates would be required to light the fire and, when this was going well, the main compressor could be rotated by a suitable starting motor in the usual fashion. Due to the heat capacity of the exchanger, the motor would be required for a longer period than with the conventional engine, but need not be any greater in capacity.

APPLICATIONS

The exhaust-heated engine can find application in any case where wide fuel utilization is important, and bulk and thermal efficiency are not prime considerations. It must be remembered that although the exchanger and combustion chamber are bulky, they must be compared with the equipment, such as gasifiers, or ash separators, or pulverizing systems that would be needed to burn solid fuel in the usual open-cycle unit. The thermal efficiency is only about 75 per cent of that of the conventional engines, but the price differential on the fuel consumable will be very much more than this, so that fuel costs will be considerably reduced. The first cost of the unit will be increased because of the larger exchanger, but in terms of cost per unit weight, the heat exchanger is about the cheapest component of the complete gas-turbine unit. The use of pure air in the turbines implies a reduction in maintenance costs, and this, together with the reduction in fuel costs, should more than make up for the extra initial cost, provided the utilization is high.

Electricity Generation. The combination of the exhaust-heated engine with steam generation, either for district heating, or extra shaft power, is most attractive. The thermal efficiency, at 36-38 per cent up, depending upon the auxiliaries, is obtained with few complications, and the plant consists essentially of a compressor, turbine, steam turbine, condenser, feed pump, vacuum pump, and combined combustor - heat exchanger - boiler.

The total transfer-surface area required will be about 2 sq ft per developed horsepower. The size of the combined heating unit for a 20,000-hp unit would be about $25 \times 25 \times 12$ ft.

If the utmost efficiency is desired, Fig. 5 shows that thermal efficiencies of very close to 30 per cent are possible, by the use of intercooling and reheat. Reheating leads to higher final exhaust temperatures, making possible higher recovery factors. With a gas-turbine efficiency of 30 per cent and 25 per cent recovery of the waste heat, an over-all efficiency of 47.5 per cent is possible. The complexity of such a plant would be less than a mercury-steam unit, and the air is much easier to handle than the mercury vapor.

It would be practical, with but very slight modifications, to burn solid or liquid fuels or low-pressure gas. In locations where low-grade fuel is very cheap, economy may be sacrificed by using a cheaper and smaller heat exchanger of lower thermal ratio. The resultant higher exhaust temperature will permit increased

utilization of the exhaust heat, so that even if the gas-turbine cycle efficiency drops to 10 per cent, the over-all efficiency of the dual-cycle plant can approach 32 per cent. Such a unit, in powers ranging up from, say, 4000 hp would be very attractive for some purposes.

Railroad Operation. Although the heat exchanger is large, it is not unreasonably so, and investigation has shown that there is enough room on a locomotive chassis to carry an exhaust-heated engine that is as powerful as a Diesel engine. A scheme for a 2000-hp unit is shown in Fig. 8. For railroad use, the ability of the same engine to run, with but minor modifications, on coal or oil may prove to be a considerable advantage, while its ability to produce steam is of advantage for car heating.

Marine Service. In very large sizes, the exhaust-heated engine probably will be too bulky to compete with the fully closed-cycle engine. Its indifference to fuel type and its convenient and economic steam production, however, render it especially suitable for ships requiring power, say, less than 20,000 shp.

CONCLUSIONS

The transposition of the combustion chamber of a conventional open-cycle gas-turbine unit to a position between the turbine exhaust and the heat exchanger results in an engine arrangement, which, although bulkier and less efficient than the usual arrangement, possesses advantages entitling it to very serious consideration for many applications. The main feature of this exhaust-heated cycle is the fact that the turbines operate on pure air, and the combustion products pass only through the heat exchanger, thus dispelling any serious fears of ash troubles or turbine-blade erosion. A further advantage is the ease with which steam can be generated from the otherwise wasted heat, permitting high efficiencies where the steam can be employed usefully.

Starting and control appear to present no serious difficulties, whether the unit is run on low-pressure gas, lump coal, or low-grade crude oil, any one of which conceivably could be burned in the same engine.

Under circumstances where the relatively large bulk of the heat exchanger and combustor present no installation difficulty, the possibility of burning really low-grade fuels—a feature assisted by the high-temperature level of combustion—makes the exhaust-heated cycle, with or without exhaust steam generation, worthy of close study. In this paper we have attempted a brief review of the more obvious aspects, and hope that it may lead to a much closer and more detailed study of some of the problems suggested.

Yellott, director of research, Locomotive Development Committee, for many valuable discussions and suggestions; and to Mr. A. G. Lane for assistance in the preparation of illustrations.

FIG. 8 DIAGRAM SHOWING A 2000-Hp EXHAUST-HEATED TURBINE IN A LOCOMOTIVE

Discussion

FREDERICK NETTEL.⁵ The basic arrangement which the author rightly recommends for many special applications is known from the time of the early air engines and was by no means overlooked when the gas turbine, or rather air turbine, created new possibilities in this field.

Since some relevant work was mentioned by reference to patents, it seems appropriate to draw attention to other work indicating new and substantial possibilities for improvement of the exhaust-heated gas turbine, by J. Kreitner and the writer.

As to Fig. 5 of the paper, it should be pointed out that the author evidently did not choose the optimum cycle which requires, after approximated isothermal compression, a temperature rise during compression

$$100 \times \frac{e(1-k)}{1-e(1-k)}$$

per cent of the absolute temperature at the start of the compression. This means that providing as the author does, for "equal temperature rise in each stage of the compressor" does not give best results. Nothing is said at what intermediate pressure reheat is applied. Optimal result requires a temperature drop during isentropic expansion, following approximated isothermal expansion, of

$$100 \times \frac{e(1-k)}{1-e^k}$$

per cent of the absolute temperature at the start of the expansion. In these formulas e is the thermal over-all efficiency of the practical cycle, and k the effectiveness of the heat exchanger.⁶

The application of the optimal hexagon cycle would have resulted in higher efficiencies than those shown in Fig. 5, or the same efficiencies with a smaller heat exchanger and smaller intercooler.

Exhaust-Heated Cycle in Practice. It seems always advantageous to divide the air leaving the air turbine into two separate streams and to use the smaller of these part streams for burning the fuel with an air surplus as used in steam boilers. The second, larger part stream is used for preheating the air coming from the compressor and leaves the plant clean. It is thus available for many uses; for example, in the chemical industries, food processing, water distillation, and the like. Only about one third of the total heating surface requires periodic servicing.⁷

The air supply proposed by the author for stoker firing is not only wasteful but unnecessary. In order to get air of suitable temperature for the coal drier in a pulverized-coal-firing plant, or air for the various compartments of a traveling stoker, it is more advantageous to tap it from the said larger second part stream at one or more points within the heat exchanger where the exhaust air has been cooled by "useful" heat exchange with the compressed air coming from the compressor to a suitable temperature or temperatures.⁸ This not only leads to considerable improvements in efficiency but also to better utilization of coal driers or of stokers, i.e., smaller stoker surfaces.

The exhaust-heated air turbine is by no means restricted to open cycles of comparatively small outputs, but can by modification to a semiclosed system be applied to plants of any size. In such high-pressure plants a turbopressure-charger set, han-

dling only about one third of the air circulating in the main high-pressure circuit, precompresses the ambient air for the main circuit. The same fraction of the hot air leaving the main turbine drives the turbine of the charger set, and after leaving the latter, is used as combustion air in the "air boiler" at near-atmospheric pressure.⁹

Another interesting application of the exhaust-heated air turbine can be envisaged in the production of large quantities of more or less heated compressed air, for example, for metallurgical furnaces. Here the air can be simultaneously sharply dried practically without additional cost, and the danger of surging of the compressor, generally associated with large fluctuations in the air demand, eliminated.¹⁰

The combination of the exhaust-heated air turbine with steam generation is surely advisable where steam is required for process purposes, district heating, etc., but from the point of view of efficiency of size of plant it does not appear necessary. It seems too early to speak of costs, but the advantage of low cooling-water requirements would surely be lost in an air-steam plant. Besides, working with two heat carriers must at best be considered an unavoidable evil in certain cases.

The cited references should, in the opinion of the writer, show that there exist no basic difficulties in burning lowest-grade oils or coals in plants of sizes which may interest the public utilities for locations where a severe shortage of cooling water exists. Improvement in plant efficiency and increase in power output during the winter months should prove another attraction.

Many of the improvements described are applicable to locomotives and can be expected to improve substantially the efficiency and performance beyond that of the arrangement proposed in Fig. 8 by the author. The decision as to the chances of the exhaust-heated air turbine for rail traction will depend on whether or not the long-awaited pulverized-coal-fired locomotive with mechanical ash removal from the compressed combustion gases will prove a success.

From the foregoing it seems possible that the present preferred position of the closed cycle for large marine plants may eventually be challenged.

We may thus conclude that the prospects for the exhaust-heated air-turbine plants are even brighter than pictured by the author.

D. G. SHEPHERD.¹¹ The author has offered a clear and concise discussion of the exhaust-heated gas-turbine cycle, a topic which as he says, has been mentioned from time to time, but has not received detailed attention.

From the practical point of view, the crucial problem is that of the heat exchanger or "air boiler" which has to handle hot gas at an entry temperature of about 1725 F, air entering at about 420 F and leaving at 1400 F. (Figures based upon the author's assumptions for a 75 per cent exchanger and 1400 F turbine-entry temperature.) The use of a counterflow arrangement involves a tube temperature intermediate between 1400 F and 1725 F and therefore it may be necessary to utilize parallel flow for the first part of the exchanger, whereby the metal temperature may be reduced to an intermediate value between 420 F and 1727 F. Under these conditions, the duty would seem comparable to that of known superheater practice, with the advantage of much lower stresses owing to the lower pressure. Some advantage in size over the conventional heat exchanger for turbine cycles can be gained from the fact that the heat exchanger is in reality an air

boiler, and a considerable part of the necessary heat transfer may be effected by radiation.

The writer has found some difficulty in arriving at the figure of 22 per cent efficiency quoted in Table 1 of the paper for the exhaust-heated cycle of 5 to 1 pressure ratio, and it seems rather high. Possibly the difficulty lies in the evaluation of pressure losses, which are quoted as 10 per cent. Does this mean a loss of 10 per cent of the maximum absolute pressure, i.e., 7.35 psi, and if so, how is this loss apportioned before and after the turbine expansion? Perhaps the author will give us in more detail his basic assumptions in calculating the cycle performance.

For some applications, it will be more convenient to have a separate power turbine whose speed can be changed from that of the main shaft. This does not alter the conclusions of the author but does lend itself to some variants of the cycle. Thus the power turbine could have a separate combustion chamber with separate air supply bled off from the compressor. For the cycle mentioned, the work ratio is approximately $1/4$, so that with the same turbine temperature and pressure-loss ratios, the air would be split such that 2 parts go through the exhaust-heated side, which would act as a gas generator, and 1 part would provide the useful power. The power-turbine side would act on the conventional cycle, requiring fuel suitable for combustion before the turbine, with the gases from the turbine either passing through a separate exchanger or mixing with the main gas stream (as they have approximately the same exhaust temperature). This arrangement is illustrated in Fig. 9 of this discussion. Such a cycle gives an

Fig. 9

efficiency intermediate between the plain exhaust-heated cycle and the plain open cycle, roughly in proportion to the amount of air by-passed to the power-output side. It does of course depart from the cycle as described, since it cannot be run entirely on solid fuel, but has the advantage of more flexibility of operation, as well as providing an intermediate fuel economy which may be useful, depending upon the ratio of fuel costs.

R. A. TYLER¹² AND D. C. MACPHEIL¹² Professor Mordel has presented an admirable introduction to an interesting gas-turbine cycle. This cycle has been the subject of a preliminary examination in these laboratories with the specific application in mind of a coal-burning power plant for locomotive use of about 5000 hp output. In a power plant of this size the air heater assumes proportions significant to the practicability of the system and various types of heater form have been investigated.

The locomotive application necessitates careful consideration of the choice of heater construction. Long service life, ease of cleaning, and maintenance are fundamental requirements. Gas-side pressure losses in particular must be kept to a minimum and volume and material requirements be of a reasonable order.

¹² National Research Council, Ottawa, Ontario, Canada.

It is believed that these requirements will best be met by a conventional shell-and-tube exchanger employing tubes of relatively large diameter for a reasonably small number of tubes under conditions of low-pressure loss. This type of exchanger can be constructed to incorporate the ruggedness necessary for locomotive operation and preliminary sketches indicate that a two-pass arrangement employing tubes as large as 1 in. in diameter can be accommodated in a locomotive layout of seventy feet over-all length. At this diameter an over-all tube run of about sixty feet would be required for a thermal ratio of 0.75 with a heat-transfer area per shp of about 3.5 sq ft. In view of the corrosive conditions and high temperatures prevailing in the shell it would appear impracticable to reduce the tube wall thickness below about 0.040 in. for a reasonable life expectation and the total weight of air heater would be about 10 lb per shp.

Stable operation and control of this form of power plant would appear to depend on a positive metering of a portion of the turbine exhaust to the firebox to effect a controlled rate of heat release, the metering being possibly effected by a simple valve of the constant-pressure type manually controlled from a "throttle" lever in the cab. This primary air in the form of hot furnace gas would be finally consumed in a separate mixing chamber with the remainder of the turbine exhaust, the mixed gases of uniform temperature proceeding to the shell of the air heater.

This physical separation of the primary and secondary air would appear desirable also from the point of view of grate-cooling requirements. The admission of fresh cooling air into the firebox must be kept to a minimum to avoid loss of over-all thermal efficiency through the rejection of this air at stack temperature. The throttle-controlled primary air entering the firebox would constitute about 25 per cent of the total turbine exhaust. The admission of cooling air into the primary air line could be effected by an automatic control of the cooling blower based on the limiting temperature (about 400°F) imposed by the grate. Under these conditions the reduction in over-all thermal efficiency due to cooling-air admission would be about 4 per cent, ignoring the negligible power requirements of the blower. The importance of controlling the cooling-air admission to a minimum level is illustrated by the extreme case in which the whole of the turbine exhaust is cooled to the limitation temperature. Under these conditions the over-all thermal efficiency would be of the order of 6 per cent.

The restriction of the firebox air to that required for the necessary heat release and the provision of a mixing chamber before the heater should result in a reduction of ash carry-over and a uniform temperature into the shell with consequent improved heater life. Further, with careful attention to the mixing-chamber design, a reduced pressure drop through the combustion system appears likely.

AUTHOR'S CLOSURE

Mr. Nettel has made many valuable suggestions for the proper application of the exhaust-heated cycle and it is obvious that he and his associates have been engaged on the close and more detailed study referred to in the conclusions.

In presenting performance calculations no attempt was made to find the optimum performance as such, we merely showed what could be done using reasonable compression ratios and maximum temperatures. For a given compression ratio equal division of the temperature rise between two stages gives the best compromise if the intercooler effectiveness be nearly unity, while in the use of reheat, practical convenience would make its application between the compressor and output turbine almost mandatory.

The suggestion to use some cooled "dilution" air to supply under the grates, rather than the separate supply envisaged by the author, is particularly valuable. The author shares with Mr.

Nettel a dislike of two heat carriers, but it seems that the rewards would make it attractive so long as water is available.

In answer to Professor Shepherd, the effect of pressure losses in the system was allowed for by assuming the expansion ratio to be 90 per cent of the compression ratio. There is thus no need to specify where the losses actually occur at this stage.

In presentation of the paper, the author eschewed discussion of all but the simplest possible engine in the interests of conciseness, but it is apparent that there are innumerable variations of more or less complexity, to suit special needs. Professor Shepherd's proposed compromise appears to the author to abandon the one selling point of the true exhaust-heated engine, namely, its ability to burn very low-grade fuels.

The possibilities of the exhaust-heated cycle obviously are going to depend on the size of a practical heat exchanger, and the comments of Mr. Tyler and Dr. MacPhail are particularly timely.

A recent report by Kays and London¹² also studies the design problems of a heat exchanger for this application, and it is of interest to compare the two solutions. Messrs. Tyler and MacPhail have considered a very rugged design whose weight comes out at 10 lb per shp, and surface area 3.5sq ft/ shp. Messrs. Kays and London have examined four cases using smaller tubes and in some cases extended surface area. The analysis suggests weight of the order 2.4–5.6 lb per shp with volumes between 67.5 and 86.3 cu ft per 1000 shp. The optimum choice of type awaits trials in service, although it would appear necessary for railroad application to use the heavier design in which, presumably, maintenance would be cheaper and simpler.

Properties and Characteristics of Fuel Oils for Industrial Gas-Turbine Usage

By D. P. HEATH¹ AND E. ALBAT,² PAULSBORO, N. J.

Largely as a result of the rapid wartime development of gas turbines for aircraft usage, renewed emphasis has been placed upon the development of gas turbines for industrial applications. At the present time a number of domestic organizations are quite active in this field. One of the principal industrial applications of gas turbines in the United States is their use in the Houdry catalytic-cracking process in the oil-refining industry. Recent development work is centered around their use in the field of locomotive and marine propulsion using either coal or oil as fuel. The ultimate choice of a fuel is a complex problem involving such factors as fuel cost, engine performance and maintenance, and fuel availability. As far as fuel oils are concerned, the designer is further confronted with a wide variety of grades from which to choose. This paper presents information on the fuel properties and characteristics which are commonly employed for the identification and specification of such fuel oils, and also on those properties which are felt to be of significance with regard to fuel-system design and combustion-chamber and gas-turbine performance. Since fuel cost and availability are intimately related to supply and demand considerations, only limited regard is given to these factors in the present paper.

TYPICAL PROPERTIES OF FUEL OILS

THE classification of fuel oils into various grades has been tried several times with only limited success. A great many differences still exist among the systems employed by various oil companies; in addition, in many cases, there are considerable differences among the fuels produced by the different refineries of one oil company. A summary of several fuel-oil classifications is given in Table 1. Three different fuel-oil classification systems are presented in this table, ASTM Burner Oils, Pacific Coast Burner Oils, and ASTM Diesel Fuels. Of these three systems the ASTM Burner Oil Classification, which also has been adopted by the National Bureau of Standards, is the most widely used.

Average properties of the fuel oils produced in the United States are given in Tables 2, 3, and 4. In these tables the average properties and the normal variation in these properties are given for four types of distillate burner fuels, three types of residual burner fuels, and for three types of Diesel fuels.

The properties of the following four distillate-burning fuels are given in Table 2:

- (a) Kerosine.
- (b) Light distillate fuel oil.
- (c) Domestic fuel oil.
- (d) Heavy distillate fuel oil.

¹ Socony-Vacuum Laboratories, Division of Socony-Vacuum Oil Company, Inc., Research and Development Department.

² Contributed by the Gas Turbine Division and presented at the Fall Meeting, Erie, Pa., September 28-30, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-F-8.

The main usage of kerosine is in wick-feed lamps and stoves, and in pot-type domestic oil burners. The main requirement of a kerosine for these purposes is good burning quality, i.e., it should burn without causing objectionable odors, smoke, or deposits. To meet this requirement, kerosine must have a boiling range of about 300 to 500 F and be paraffinic in nature.

Light distillate fuel oil is a product that is very similar to kerosine in physical properties. However, it usually will not meet all of the rigid kerosine specifications. Light distillate fuel is used mainly in pot-type domestic oil burners. Both kerosine and light distillate fuel oil frequently are sold as light Diesel fuels.

Domestic fuel oil is the most widely used distillate fuel. It has a boiling range of about 400 to 700 F and is used in all types of domestic oil burners. To burn satisfactorily in most domestic oil burners, a fuel should have an ASTM 90 per cent point below 675 F, as fuels having appreciable amounts of material above 675 F tend to smoke and leave deposits in those burners of poorer design. In addition, domestic fuel oil should be noncorrosive and should not deposit gum or sediment in the burner, fuel lines, or fuel tank.

A few types of domestic oil burners can burn satisfactorily a fuel of slightly higher boiling range than domestic fuel oil. In some localities heavy distillate fuels are available for use in these burners. Heavy distillate fuels have boiling ranges of about 400 to 750 F and have somewhat higher heats of combustion on a volume basis.

The properties of light and heavy No. 5 fuel oils and No. 6 fuel oils are given in Table 3. These stocks all contain residual materials and are used as industrial and marine fuels. The chief physical requirement of these fuels is that they be sufficiently fluid to permit ready transfer by pumping. For this reason, the classification of fuels into light and heavy No. 5 and 6 types was made on the basis of viscosity. The No. 5 fuel oils can be pumped without heating, except during extremely cold weather. The No. 6 fuel oils usually require heating to considerably higher temperatures than No. 5 fuel oils.

Typical physical properties of light, medium, and heavy distillate Diesel fuels are given in Table 4. The two major requirements of Diesel fuels are ignition quality, as measured by cetane number, and volatility. In certain critical Diesel engines (high-speed) the more volatile fuels give less exhaust smoke and odor, and fuels of high cetane number promote easier starting and smoother operation. Inasmuch as Diesel engines of a wide variety of sizes and speeds are produced, the volatility and cetane-number requirements vary considerably.

Light Diesel fuel is of the same boiling range as kerosine. Frequently, to simplify supply and distribution problems, a product meeting the requirements of both water-white kerosine, and light Diesel fuel is produced and sold as a common fuel grade. Similarly, domestic fuel oil is sometimes sold as medium Diesel fuel.

Specifications for the three highest-quality fuels—kerosine, medium Diesel fuel, and domestic fuel oil—are quite rigid; hence the range of properties encountered among several samples of these fuels is much narrower than will be encountered with most other fuels. The properties of residual fuel oils, in particular, will vary over a wide range.

All of the ten classifications of oils listed in Tables 2, 3, and 4 are not available in any one locality. In most localities in the United States three to seven classifications of fuel oils will be available. The three fuels that are most widely distributed are kerosine, domestic fuel oil, and No. 6 residual fuel. Some changes in the availability of oil stocks can be expected from year to year, but residual fuels will continue to be the most plentiful, with domestic fuel oil being the most widely available distillate fuel.

SIGNIFICANCE OF PHYSICAL TESTS

In studying various physical tests of fuel oils, it should be kept in mind that no one test taken alone is of much value, but that a group of tests is necessary before the characteristics of the oil can be evaluated. With this in mind, the significance of the various tests listed in Tables 1 through 4 are discussed briefly.

API Gravity. API gravity is a direct measure of the density of an oil and is a good indication of its heating value. The density of an oil changes rather rapidly with temperature. Fig. 1 is useful in estimating the density at various temperatures when the API gravity is known. API gravity is also an indication of the composition of an oil. For example, of two oils having the same boiling range, the one having the higher API gravity is the more paraffinic.

ASTM Distillation. An ASTM distillation is one of the most common tests conducted on petroleum products. It is a measure of the boiling range of an oil and, as such, is of different significance with different products. In domestic fuel oils the amount of high-boiling material present gives an indication of the performance of the oil in certain types of burners. Specific burner types are commonly designed to operate on fuels of a given volatility. Use of a fuel higher in boiling range than that for which the burner was designed usually will lead to increased smoke and deposits. For example, most gun-type household burners can burn successfully a heavier fuel than pot-type burners, while an industrial-type burner can burn practically any liquid fuel.

FIG. 1 DENSITY CHARACTERISTICS OF FUEL OILS

Flash Point. The flash point of an oil is the lowest temperature of the oil at which the vapor above the oil will burn if subjected to an open flame. Therefore the flash point of an oil is an indication of the temperatures at which an oil can be handled without undue fire hazard. Both the Pensky-Martens and Tag flash points, listed in Table 2, are determined in a closed container and agree quite well with each other; however, the Tag flash point procedure should not be used for oils having flash points above 175 F. The flash point determined in a closed container is always a few degrees lower than a flash point determined in an open container.

Viscosity. Several different methods of measuring viscosities are used for fuel oils, each grade of fuel oil having a particular viscosity method that is most widely used in its specification as shown in Table 5.

Kinematic viscosity at 100 F is gradually replacing the various Saybolt viscosity measurements as it is a more accurate and more

TABLE 5 METHODS OF MEASURING VISCOSITY

Product	Type viscosity measurement usually specified
Kerosine.....	Saybolt thermo viscosity at 60 F
Diesel fuels.....	Saybolt Universal or kinematic viscosity at 100 F
Distillate fuel oils.....	Saybolt Furol viscosity at 122 F
Residual fuels.....	Saybolt Furol viscosity at 122 F

flexible method of test. Kinematic viscosity at 100 F can be converted to the various Saybolt measurements by means of the scales given in Figs. 2 and 3. Typical viscosity-temperature curves for the various grades of fuel oil are also given in these figures. Since No. 6 fuel oils cover such a wide range of viscosities, two lines are given for this grade.

A lower limit of 30-sec Saybolt Universal at 100 F on Diesel fuels is generally recognized as being necessary to prevent leakage in worn fuel-injection equipment, and to furnish lubrication for the injection equipment of certain types of engines. For operation at atmospheric temperatures below 10 F, high-viscosity fuels are usually avoided to secure the required low pour point and increased volatility. If the viscosity of a Diesel fuel is unusually high, a solid stream may be obtained from the injector instead of a spray.

In the utilization of residual fuels in marine boilers, which usually do not have steam atomizers, an optimum viscosity of the

fuel at the nozzles can be found which results in the most efficient combustion. Preheating of viscous boiler fuels to give a viscosity of about 150 sec Saybolt Universal at the sprayer plates is standard U. S. Navy practice.

Detailed relationships of the effects of viscosity upon spray characteristics of gas-turbine fuel nozzles are not available, but it is expected that the design of the atomizing equipment will provide no difficult problem.

Viscosity is also related to ease of pumping. In general, if an oil has a viscosity of over 5000 to 10,000 sec Saybolt Universal, it is extremely difficult to pump. Inasmuch as the viscosity of an oil decreases rapidly as the oil is heated, very viscous oils require heating before they can be pumped. The temperatures to which an oil of a given viscosity must be raised to facilitate easy pumping can be estimated by the use of Figs. 2 and 3.

Pour Point. The pour point of an oil is the lowest temperature at which an oil will flow under specified test conditions. It is related directly to the wax content and viscosity of an oil. In general, the lowest practical pumping temperature is considered to be about 10 deg F above the pour point.

Aniline Cloud Point. The aniline cloud point is a measure of the paraffinicity of an oil, a low aniline point indicating an aromatic, naphthenic, or a highly cracked oil. Conversely, a high

FIG. 2 VISCOSITY CHARACTERISTICS OF REPRESENTATIVE FUEL OILS

FIG. 3 VISCOSITY CHARACTERISTICS OF REPRESENTATIVE FUEL OILS

aniline point indicates a paraffinic straight-run oil. The major use of the aniline point is in the calculation of empirical constants related to some performance characteristics. These constants are discussed in a later section of this paper.

Sulphur Content. From a corrosion standpoint, sulphur content is important only when it is excessive. It must be remembered that sulphur occurs in many forms of which some are harmful and some are not.

The sulphur content of kerosines, which are to be burned in lamps or stoves indoors obviously should be quite low because of the resultant odor of the products of combustion. However, the sulphur content of other burner fuels is not of importance from the standpoint of corrosion in the exhaust or chimney unless the products of combustion are cooled sufficiently to condense the water in them. Sulphur dioxide is not a corrosive agent except in the presence of water.

With respect to corrosion at high temperatures, of the order normally encountered in gas-turbine applications, Avery (1)² presents quantitative data showing the effects of sulphur-bearing combustion gases on various metal alloys. It was shown that even high-sulphur gases do not cause a measurable increase in corrosion rate over that which would be obtained with air of the same temperature, when high-temperature-type alloy steels are used.

Copper-Strip Corrosion. Copper-strip corrosion tests attempt to measure the corrosive tendencies of an oil. Usually such tendencies are related to the presence of harmful sulphur com-

pounds. The results of corrosion tests are obvious for very bad fuels or very good fuels, but intermediate cases are not conclusive. The corrosion occurring in a system handling fuel oil is more frequently the result of the existing temperature-humidity conditions or the materials of construction rather than the result of operation on a corrosive fuel.

Color. The color of an oil is of little value as an indication of its performance characteristics except in extreme cases wherein contamination is indicated. The two common methods of measuring the color of petroleum oils are the Saybolt and ASTM methods. The Saybolt colorimeter is used on white products such as kerosine and gasoline. The Saybolt color scale runs from -16 (darkest) to +30 (lightest). The ASTM colorimeter is used to measure the color of fuel and lube oils. On the ASTM color scale, No. 1 is the lightest and No. 8 is the darkest color.

Water and Sediment. The presence of water and sediment is usually an indication of fuel-oil contamination. In the case of residual fuels, high values for this test may also be related to the instability of the fuel which is occasioned by the precipitation of heavy asphaltic or carbonaceous substances. The sediment-by-extraction test is another test frequently specified for heavy fuel oils and is supposed to give a similar indication of the insoluble material dispersed in the oil which ultimately will sludge out. Neither of these tests has been found to correlate with the pre-heater fouling characteristics of certain residual fuel oils. Presumably, polymerization and oxidation effects associated with the frequent recirculation of oil at relatively high temperatures over-balanced these factors. As a result, the Navy Department, in specifying stable residual fuel oil for its vessels, requires that it

² Numbers in parentheses refer to the Bibliography at the end of the paper.

pass a heater-fouling test which simulates preheater operation aboard ship.

Another well-known cause of sludge and sediment in fuel oils is that resulting from the incompatibility of mixtures. A gross example of this would be the mixing of a straight-run Diesel fuel with a deeply cracked bunker C fuel oil. Though neither fuel would have large amounts of sediment present, as indicated by the BS&W test, the mixture would have a very large amount which could plug lines, filters, and preheaters. Vessels are particularly susceptible to this type of fuel failure where bunker liftings from different countries are made. Where there is doubt concerning the compatibility of fuel oils, segregation of the stocks will of course minimize operating difficulties.

Ash Content. Residual fuel oils usually possess ash-forming constituents which indicate the presence of inorganic materials. A wide variety of metals may be found in the ash which originates in part from the metals inherent in the crude oil, the contamination by chemical compounds during the refining operation, and the entrainment of materials such as rust, seawater, etc. Sodium, iron, and vanadium are particularly deleterious to the brickwork in a furnace and cause rapid slagging of the refractory materials, necessitating frequent and costly replacement. In addition, these materials in the form of sulphates and oxides deposit on the closely packed superheater tubes and restrict the passage of the combustion gases through the furnace.

In so far as gas-turbine operation is concerned, a high ash content in the fuel oil may increase the rate of erosion of the burner chamber, turbine nozzles, and blading. In a recent test (2) with a high-ash-content fuel (1.5 per cent) no serious effects were noted. Efforts on the part of the refinery to reduce the ash in residual fuels have not been successful without a disproportionate increase in the cost of the fuel. Filtration and centrifuging were found to be partially effective, depending on the nature of the oil and the ash-forming constituents as well as the conditions of processing.

Carbon Residue. The carbon residue of distillate-type fuels is generally too small to be measured accurately. The carbon-residue test on the 10 per cent bottoms from the fuel is more reproducible and serves to indicate the presence of residual materials. Carbon residue has some relation to burner deposits caused by fuel oils and is felt to be related to combustion-chamber deposits in Diesel engines; however, no definite relationship has been found. In residual fuel oils, a high carbon residue indicates a deeply cracked fuel oil or, in some cases, residual materials from highly asphaltic crude. Paraffinic straight-run residual fuel oils are characterized by a relatively low carbon residue.

Heat of Combustion. The heat of combustion of an oil is usually estimated from the API gravity inasmuch as the actual determination is quite difficult. Fig. 4 shows the relationship between API gravity and the net or lower heating value. In general, the differences in heat of combustion between different batches of the same grade of fuel are too small to be reflected in engine or burner performance. However, in carefully controlled laboratory tests of Diesel engines, heat of combustion has been found to be a variable affecting power output and fuel consumption.

Cetane Number. Cetane number is of importance only in Diesel fuels. It is one of the factors affecting engine starting and roughness in operation, but appears to have little or no direct relation to exhaust smoke, power, or fuel consumption.

Heat Content and Related Thermal Properties. The thermal properties of fuels, such as heat content, heat capacity, and thermal conductivity, often must be estimated in the design of fuel-oil systems. Average values for these variables are given in Figs. 5 to 7, inclusive, which should prove useful to the design engineer.

Spontaneous-Ignition Temperature. A measure of the ease with which an oil will ignite in contact with a hot object in the presence of air is given by the spontaneous-ignition temperature.

FIG. 4 HEAT OF COMBUSTION OF PETROLEUM FRACTIONS AT CONSTANT PRESSURE

It is not entirely a fuel property, however, as the values will vary considerably depending upon the apparatus used and the method of test employed. As an indication of the values obtained, some of the results of Edgar (4) are given in Table 6.

Surface Tension. Surface tension is the molecular force existing in the surface film of all liquids which tends to contract the volume into a form having the least surface area. Compared to water, petroleum products have relatively low surface tensions. Water has a surface tension of 76 dynes per cm at 20 C (68 F), while petroleum products have surface tensions varying from 15 to 40 dynes per cm at 20 C.

TABLE 6 SPONTANEOUS IGNITION TEMPERATURE OF PETROLEUM PRODUCTS (4)

Diesel fuel (45 cetane).....	790
No. 1 fuel oil (Mid-Continent).....	530
SAE 60 aero lube oil (MC solv. ext.).....	750

This property in petroleum distillates appears to be a direct function of the density of the oil. In Fig. 8 the surface tensions of a number of pure hydrocarbons boiling in the gasoline range (5) are plotted against specific gravity. The line drawn in Fig. 8 is that given for petroleum distillates having end points up to 570 F (6).

The surface tension of petroleum products decreases with increasing temperature. From the limited amount of data available, it appears that all types of hydrocarbons have approximately the same rate of change of surface tension with temperature. In the range of 0 to 100 C (32 to 212 F), this rate of change is approximately 0.11 dynes per cm per deg C (0.061 dynes per cm per deg F).

In aqueous solutions, the addition of wetting agents or detergents causes an appreciable reduction in the surface tension of the liquid and gives a solution which will form a relatively stable froth with air. In petroleum products, however, the addition of antifoam agents or surface-active agents brings

Fig. 5 TOTAL HEAT CONTENT OF PETROLEUM FRACTIONS (Average stock.)

Fig. 6 HEAT CAPACITY OF PETROLEUM FRACTIONS (Average stock.)

Fig. 7 THERMAL CONDUCTIVITY OF PETROLEUM LIQUIDS

about a reduction of less than 3 dynes per cm in the surface tension of the oil. Inasmuch as the surface tension of a petroleum distillate of a given boiling range will fall within a relatively narrow range, and this range can be changed only slightly by the use of addition agents, the surface tension of a fuel oil would ap-

Fig. 8 SURFACE TENSION OF PETROLEUM OILS

pear to be a very minor variable affecting the characteristics of the fuel spray from a nozzle.

OTHER CHARACTERISTICS AND TESTS

Empirical Constants. It is apparent that the performance characteristics of an oil are quite difficult to estimate from the usual physical tests. Since performance tests are quite difficult and expensive to make, several empirical constants utilizing two or more physical tests have been developed for estimating product performance. These constants usually employ two or more of the following properties: API gravity, viscosity, aniline cloud point, and average boiling point. Since all of these properties are interrelated, the use of two of them is usually sufficient to obtain an indication of the composition of an oil and hence of its performance properties.

Diesel Index. Diesel index is a relatively reliable index to cetane number. It is usually several numbers higher than the corresponding cetane number, except in the case of fuels containing additives to improve the cetane number in which case the relationship may be reversed.

The relationship between Diesel index and cetane number is about as follows

Diesel index	Cetane number
43	40
50	45
59	50

Diesel index is applicable only to fuels having a boiling range similar to that of Diesel fuel. For example, aviation gasoline has a Diesel index of about 70, and a cetane number of below 10.

Diesel index is calculated from the API gravity and the aniline cloud point by the following equation

$$\text{Diesel index} = \frac{\text{API gravity} \times \text{aniline point, deg F}}{100}$$

UOP K-Value. The UOP K-value or characterization factor has been widely used as an index of composition in the correlation of thermal properties, such as heat content and specific heat of oils. It has also been used to indicate the burning qualities of fuel oils. The range of values obtained is quite limited. Most oils will be between 10.0 and 12.5 with the paraffinic stocks having the higher values. The K-value is calculated from the aver-

age boiling point and specific gravity by the following equation

$$K = \frac{\sqrt[3]{T_B}}{S}$$

where

$$T_B = \text{average boiling point, deg F} + 460$$

$$S = \text{specific gravity } 60/60 \text{ deg F}$$

Carbon-Hydrogen Ratio. The carbon-hydrogen ratio of distillate fuels has been found to correlate with the carbon deposits formed in domestic oil burners under certain operating conditions. Here again, the design of the burner is of primary importance and, in critical units, fuels having low carbon-hydrogen ratios, i.e., the more paraffinic fuels, will result in smaller deposits.

The carbon-hydrogen ratio of a fuel can be determined by burning a given amount of oil completely and analyzing the products of combustion. However, this procedure is extremely difficult to carry out accurately. A correlation for estimating carbon-hydrogen ratios of distillate fuels has been developed by Cauley and Delgass (7) and is presented in Fig. 8. This correlation is based upon aniline point, API gravity, and boiling point of a fuel (ASTM 50 per cent boiling point). The empirical formula expressing the relationship in Fig. 9 is as follows

$$C/H \text{ ratio} = \frac{28}{\sqrt{A + 47}}$$

Application of this correlation is limited to distillate fuel oils with mid-boiling points ranging from 350 F to 671 F.

PRODUCTION OF FUEL OILS

The production of fuel oils, in general, is controlled by refining

FIG. 9 CARBON-HYDROGEN RATIO OF DISTILLATE FUEL OILS

operations for the production of more valuable products. Fuel oils, ranging from light domestic fuel and high-speed Diesel fuel, to heavy marine and industrial fuel are obtained as distillates, or as residuum from primary crude-oil distillation, or from thermal and catalytic cracking. All types of fuel oils can be converted to gasoline by thermal or catalytic cracking, assuming the availability of suitable processing equipment.

Since refining operations are ordinarily carried out primarily to obtain the desired yield and quality of gasoline, it is not possible to exercise complete control over the characteristics of the fuel oils produced simultaneously. In the case of crude-oil distillation, the light-fuel boiling range can be controlled, but not much can be done about any of the other characteristics. In other words, the refiner simply isolates a fuel of desired boiling range and its characteristics depend only on the type of crude processed. In the case of heavy fuels, the chief property which can be regulated is viscosity. This characteristic is controlled by blending light fuel-oil (distillate) fractions in the residual (undistilled) fuel to the extent required. Similarly, the light fuel produced by thermal and catalytic cracking can be controlled as regards boiling range, but the other characteristics depend primarily on the type of stock being processed and on the severity of the cracking operation. The viscosity of the heavy fuel produced through thermal cracking is regulated, as in the case of crude-oil distillation, by blending-in light fractions. Thus the production of fuels of the desired characteristics is mainly a matter of selection and blending of available stocks.

The stability and performance specifications for kerosine, Diesel fuel, and domestic heating oils limit the types of refinery stocks suitable for these fuels. In general, burning kerosines contain only straight-run material, light Diesel fuel contains straight-run and catalytically cracked fuel, and domestic fuel oil can contain straight-run, catalytically cracked, and thermally cracked fuel.

AVAILABILITY OF FUEL OILS

It is difficult to predict reliably what the future relationship of supply and demand for fuel oils will be. With the completion of refinery-expansion programs, and the modernization of transportation systems, supply has more than kept up with demand. The result has been a cutback in crude-oil production today. The fact remains that, when needed, enough oil will be produced to satisfy all essential requirements in the near future, despite the predictions of some forecasters to the contrary.

An estimate of the future fuel-oil balance can be made from current consumption trends. For 1947, Table 7 (8) gives the consumption of fuels in the United States. It is noted that heating and industrial applications were the principal consumers of fuel oils. Residual fuels constituted the bulk of the oils and averaged about 56 per cent of the total; distillate fuels came next and comprised about 25 per cent. Kerosine and Diesel fuel made up the remainder of 11 and 8 per cent, respectively. At the moment, domestic oil-burning installations are proceeding at an accelerated rate which, together with the steam-to-Diesel con-

version program of the railroads, and the increased use of Diesel tractors, buses, and trucks, will impose increased demands on distillate-type stocks. The extent of these increases for 1951 is estimated in Table 8.

A reduction in the amount of residual fuel oils available is predicted. However, they will still be the main fuel-oil type for some years to come. Part of the increase in distillate fuels will be accomplished at the expense of residual stocks which will be cracked more extensively. In the immediate future, considerations of supply point to the use of these residual grades as the most attractive liquid fuel for gas-turbine usage.

Discussion

F. T. HAGUE.³ The total fuel cost for an industrial gas turbine must not exceed that of a Diesel engine if the gas turbine is to be a competitive engine. This means that it must burn residual oil. Residual oils as a group have two characteristics which must be controlled to insure satisfactory use. These are (1) the compatibility or freedom from sludge formations when batches of different origin and history are mixed together; and (2) the ash content of metallic salts which adheres to turbine blading and renders units inoperative.

In reference to the use of residual oil, it should be recognized that any gas-turbine manufacturer can develop a combustor for efficient combustion, and that the turbine-blade deposits, resulting from the use of an unsuitable batch of oil, are independent of the combustor design or the name of the turbine manufacturer. The problem of avoiding the use of unsuitable oil in a gas turbine has the characteristics of an industry problem, in that it is in the interest of the customer, the oil supplier, and the turbine manufacturer that the impossible not be attempted.

The industrial gas turbine gives promise of being a continuous outlet for a nominal percentage of residual oil. The oil industry's interest in developing this outlet for the otherwise surplus "what's left" of the refining process is commendable in all respects. Let's

consider the wealth of information at their disposal to do something constructive for the gas-turbine fuel-oil problem.

The oil suppliers know the field origin and the processing history of their residual oils. They recognize the typical ash content of the crudes from specific oil fields, such as the objectionable vanadium pentoxide from South America, and the sodium and calcium sulphates from domestic fields. We understand they recognize the impossibility of mixing refinery stocks from straight-run catalytically or thermally cracked processes without incurring incompatibility. This general type of information and experience is the present basis for preparing Navy Special residual oil.

The gas-turbine group must now become sufficiently articulate to tell the oil industry what it requires of a gas-turbine residual oil. Once the oil industry is convinced there is a gas-turbine residual-oil problem and takes the necessary steps to segregate and market a suitable "gas-turbine residual oil," it will be using its potential technical knowledge and experience most commendably. There is every indication that the various oil suppliers should get together and pool their experiences so that the availability of a gas-turbine residual oil fuel is a reality of tomorrow. Diesel oil fuel is closely controlled by specification because the Diesel and oil industries recognize the common-sense economics of using a suitable fuel. The gas-turbine industry is yet in the embryo stage, but the same common sense should rapidly mature the thinking on its fuel problem. Customers aren't going to like it otherwise.

ASHTON HOWARTH.^{4,5} More emphasis, it is believed, should be placed on ash content and its effects, as it constitutes one of the principal objections militating against the use of residual-type fuels in gas turbines. Serious as the corrosion problem may be, it is probable that susceptibility to attack by and deposition of vanadium compounds and other salts also are of great importance. Part of this problem is not much different from that encountered in steam-boiler practice where deposition of materials in the forms of sulphates, glasses, and oxides in superheater banks restricts the passage of combustion gases through the boiler and interferes with its operating efficiency.

The authors cite an example where a high-ash-content fuel produced no serious effect. Type of constituent is even more important than the amount; a low ash content of certain constituents can be much more offensive than higher amounts of other materials. Published analyses show one of the most bothersome constituents to be sodium sulphate.

Hughes and Voysey⁶ describe in great detail the ash and deposits found on gas-turbine blades and show that sodium is the most likely to form harmful deposits. They also discuss the various processes by which the ash adheres to the blades and possible means of dealing with this problem.

In connection with possible corrective measures, it is not to be overlooked that if the ash constituents are present in the vapor phase, their removal by mechanical means such as filtration is impractical.

E. W. JERGER.⁷ It is indeed true that the C/H ratio is difficult to obtain by a method of burning the fuel and analyzing the

³ Consulting Engineer, Steam Division, Westinghouse Electric Corporation, Lester Branch, Philadelphia, Pa.

combustion products. At present there is not available gas-analyzing equipment to enable one to make an extremely precise exhaust-gas analysis in oil burning. Then, in the calculation of the C/H ratio it would have to be assumed that the fuel is composed of only carbon and hydrogen. Ordinary heavy commercial distillates, even if low in sulphur content, rarely have greater than a 97 per cent combined carbon-hydrogen content. The aniline point and the (UOP) K factor, in fact, both are a measure of the paraffinicity of the oil. Hougen and Watson⁸ have shown that the K factor, average boiling point, and API gravity are related to the molecular weights of petroleum fractions. In general, paraffinic fractions have higher molecular weights than aromatic fractions with corresponding lower K factors, at approximately the same average boiling point. A correlation is also given between the hydrogen content and the K factor plus one other property. It seems that the C/H ratio with the molecular weight would indicate the general chemical structure of the compound.

The 50 per cent distillation temperature should only be used as the average boiling point for petroleum fractions of the same crude. A mixture of different-gravity distillates will exhibit a wide boiling range.

The writer takes exception to the correlation cited between Diesel index and cetane number. While the aniline point correlates well with the cetane number, the usual differences in API gravity for fuels taken from the same crude destroys a good correlation between the Diesel index and cetane number.

One property the author didn't mention that may have a bearing on the combustion-chamber design, from a combustion time standpoint, is the heat of vaporization. The heat of vaporization has also been empirically related to API gravity and boiling point, and can of course be calculated with the classical Clapeyron equation.

In regard to the mention of preheating fuel oil supplied to a burner; it has been the writer's experience that the preheat temperature should correspond to an optimum viscosity. The optimum viscosity seems to be a matter of droplet size, and is best found by experiment. Preheating a heavy residual No. 6 fuel oil to approximately 180 to 190 F seems to give the best results.

AUTHORS' CLOSURE

From the limited experimental and operational data available,

⁸ "Chemical Process Principles," Part 1, by Hougen and Watson, John Wiley and Sons, Inc. New York, N. Y., 1943.

the fuel problems associated with the use of residual fuels in gas turbines are by no means clear cut. Both railroads and merchant vessels, which are substantial consumers of residual fuels, have not suffered incompatibility difficulties though their fueling points cover a wide geographic area. The insistence of the Navy Department on a compatibility specification for its boiler fuels is probably based on the much greater area its vessels would be expected to cover as well as the necessity for minimizing operating difficulties however remote their possibility. Consequently, very few instances of incompatibility are anticipated in the utilization of residual fuel oils in gas turbines.

Hughes and Voysey in some commendable experiments did show that certain elements in fuel oils contribute more to turbine deposits than others. In their work with a 500-hp experimental gas turbine, deposit formation on the turbine blading was found to be progressive. Other turbine users, however, found that some deposits reached a maximum thickness and then remained constant indicating that operating conditions and turbine design were factors related to this phenomenon. The recent work of Buckland and Barkey on a 4800-hp commercial gas-turbine unit apparently did not lead into any deposit problems in the turbine even though residual fuels of varying ash contents were used. Corrosion, however, was encountered with a high-ash fuel containing vanadium. It is evident that more operating data on industrial gas turbines are needed to evaluate the effects of ash.

It is difficult to follow Jerger's contention that the 50 per cent distillation temperature should be used as the average boiling point only for petroleum fractions of the same crude. The C/H ratio correlations cited in the paper were developed from a series of 22 distillate fuels covering different crude oils and different refinery processing methods. The average deviation of estimated from actual C/H ratio was found to be 0.89 per cent and the maximum deviation was 3.27 per cent.

The aniline point of Diesel-fuels has not been found to correlate well with the cetane number. An estimation procedure utilizing only the 50 per cent boiling point and the API gravity⁹ of a fuel has been found to give acceptable estimates of cetane numbers for most fuels. The Diesel index correlation was presented because of its use as an alternate to the cetane-number requirement in a number of specifications.

⁹ "The Correlation of Cetane Number With Other Physical Properties of Diesel Fuels." Report by the Diesel Index Panel of Standardization Subcommittee No. 4, Gas Diesel & Fuel Oils, *Journal of the Institute of Petroleum*, vol. 30, 1944, p. 193.

Combination of Heat Sources and Sinks by the Method of Superposition¹

By F. H. BRIDGERS,² LOS ALAMOS, NEW MEXICO

A superposition method is proposed whereby the temperature pattern around a single buried heat source at a given temperature is used to arrive at the pattern obtained when several heat sources at the same temperature are placed at any distance apart. An equation is derived to give the "strength ratio," which is defined as the ratio of heat dissipated by one of a series of buried heat sources of equal temperature to the heat dissipated by a single heat source at the same temperature. This equation is plotted for a specific case to show the "strength ratio" as a function of heat-source spacing. Experimental temperature-distribution patterns around a heated tube buried in a box of sand are shown for the center tube of a group of three tubes. Although the proposed superposition method is subject to an inherent error, which may be severe at very close spacing of heat sources, the agreement between experimental and calculated results for the cases investigated in this work is good.

NOMENCLATURE

The following nomenclature is used in the paper:

A = distance from center of tube to "near" surface of equivalent slab

$$A = a + \frac{k_a}{f}$$

a = distance from center of tube to near surface in actual slab

B = distance from center of tube to "far" surface of equivalent slab; $B \gg A$

d = distance between tubes (center to center)

f = combined radiation-convection heat-transfer coefficient

$f(x, y)$ = mathematical function defined by Equation [1d]

$f(x, 2A-y)$ = mathematical function defined by Equation [1e]

k = thermal conductivity

k_a = thermal conductivity of equivalent slab

\ln = natural logarithm

q = heat flux per unit length of source

r = distance from line source or sink

r_0 = radius of cylindrical heat source

r_1, r_2, r_3, r_4 = distances from a particular line source or sink

$t_{x,y}$ = temperature of a point in a slab

t_w = temperature of tube surface

t_a = effective temperature of environment on heating side of slab; approximately equal to $\frac{t_a + t_s}{2}$

t_a = air temperature on heating side of slab

t_s = average surface temperature of surroundings on heating side of slab

t_e = effective temperature of environment on nonheating side of slab

α = constant defined by Equation [1a]

β = constant defined by Equation [1f]

γ = constant defined by Equation [1i]

Δ = constant defined by Equation [1b]

θ = temperature potential (point temperature minus sink temperature)

$\theta_0, \theta_1, \theta_2$ = temperature potentials due to a particular line source or sink

θ_p = temperature potential due to a combination of line sources or sinks

η = "strength ratio" defined as ratio of heat dissipated by one of a series of buried heat sources of equal temperature to heat dissipated by a single heat source at same temperature

π = mathematical constant, = 3.14159 . . .

$\psi(x, y)$ = mathematical function defined by Equation [1e]

$\psi(0, -B)$ = constant defined by Equation [1h]

$\psi(r, 0)$ = constant defined by Equation [1g]

INTRODUCTION

The solution of heat-transfer problems involving the two-dimensional steady flow of heat from a single heat source in a solid medium has been proposed by Carslaw (1)³ and others (2, 3). The various solutions are exact only when the boundaries of the solid mediums are isothermal sinks. For the case where the boundary of the solid medium is not isothermal, such as a pipe or cable buried in a wall, the solution is greatly complicated because of the complexity of establishing exact boundary conditions. Schofield (4) has shown that approximate solutions of such problems are possible by establishing simplified approximate boundary conditions. If there exists, instead of a single heat source, a series of heat sources at the same temperature buried in a slab, the mathematics of the problem becomes much more involved. This work will deal principally with the approximate solution of the type of problems where a series of cylindrical heat sources at the same temperature are buried in a solid medium. A practical example of such a case would be that of a floor-heating panel having hot water pipes buried in concrete. The boundary of the solid (panel surface) for the case considered will not be an isothermal sink, but will have a surface temperature distribution being governed by the balance at each point of the heat conducted to the surface from heat sources and that transferred from the surface by convection and radiation.

Vanderweil (5) has derived an equation to give the two-dimensional temperature distribution in a slab containing equally spaced heated tubes at the same temperature. His equation holds only when the tubes are located very near to one of the bounding surfaces of the slab, so that the percentage of heat flow

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-F-13.

³ Numbers in parentheses refer to the Bibliography at the end of the paper.

$$\theta_p = \theta_0 + \theta_1 = \frac{q}{2\pi k} \ln \frac{r_2}{r_0} + \frac{q}{2\pi k} \ln \frac{r_4}{r_3} \quad \dots\dots [4]$$

$$\theta_p = \frac{q}{2\pi k} \ln \frac{r_2 r_4}{r_0 r_3}$$

If the isothermal at r_0 represents the surface of a pipe with constant water temperature, the temperature potential at P will remain constant at θ_0 regardless of how close line source B ap-

FIG. 2 COMBINATION OF TWO HEAT SOURCES IN AN INFINITE SLAB

proaches source A ; therefore Equation [4] does not hold. It is foreseeable that the strength, q (B hr⁻¹ ft⁻¹ of length), of each individual source, when combined with other sources in the solid at the same temperature will be less than the strength of the individual source alone in the solid. In other words, if two pipes at the same temperature were placed close together in a solid, each individual pipe would dissipate less heat than if one of the pipes were alone at the same temperature. Therefore, by fixing the temperature potential at r_0 , for the case of two sources close to one another, Equation [4] should be written in the form

$$\theta_p = \theta_0 = \eta \frac{q}{2\pi k} \ln \frac{r_2 r_4}{r_0 r_3} \quad \dots\dots [5]$$

where η is the "strength ratio," defined as the ratio of heat dissipated by one of the two tubes when together, to that dissipated by the same tube when by itself and at the same temperature.

Solving for η in Equation [5]

$$\eta = \frac{\theta_0 2\pi k}{q \ln \frac{r_2 r_4}{r_0 r_3}} \quad \dots\dots [6]$$

Solving for q in Equation [4] and substituting in Equation [6], we obtain

$$\eta = \frac{\theta_0}{\theta_0 + \theta_1} \quad \dots\dots [7]$$

In Equation [7], θ_0 is fixed as the difference between the temperature of the source and the temperature of the sink, while θ_1 is evaluated by means of Equation [3]. Equation [3] is given in terms of x, y -co-ordinates by Boelter and coworkers (6). Equation

[7] provides a good approximation for the change in strength q (B hr⁻¹ ft⁻¹ of length) of two pipes as a function of their distance apart in a slab. For the limiting case of two pipes when the distance apart approaches zero, η will approach 0.5, as would be expected for equal temperature pipes. As the distance apart increases, η will approach 1.0. The foregoing treatment is not limited to two pipes but could be applied to a series of pipes, and the decrease in strength of a single pipe could be similarly computed.

In applying the analytical treatment to an air-cooled slab with a series of embedded tubes, only an approximate solution can be obtained because of the complexity of establishing true boundary conditions. Equation [3], which was used to obtain Equation [7], holds only when the slab is bounded by an isothermal plane. Such is not the case for a finite slab with embedded tubes, but rather there is a definite surface-temperature gradient between the adjacent tubes. Vanderweil proposed approximate boundary condition in developing his theoretical equation which we may employ in the analytical approach of this treatment. He considered the actual slab, including the combined surface radiation-convection film, to be replaced by an equivalent slab of constant conductivity, which has the same resistance to heat flow as the actual slab. Such an equivalent slab is shown in Fig. 1 where the heat flow through the back side of the slab is neglected. If we assume the strength of three sources to remain unchanged upon combining, the temperature at point P , Fig. 1, would be

$$\theta_p = \frac{q}{2\pi k} \left[\ln \frac{r_2}{r_0} + \ln \frac{r_2}{r_1} + \ln \frac{r_4}{r_3} \right] \quad \dots\dots [8]$$

The strength ratio for the center tube can be obtained in the same manner as used to obtain Equation [7]

$$\eta_A = \frac{\theta_0}{\theta_p} \quad \dots\dots [9]$$

For an infinite number of equally spaced tubes the temperature potential at any point in the slab will be

$$\theta = \eta \frac{q}{2\pi k} \left[\ln \frac{r_1}{r_2} + \ln \frac{r_2}{r_4} + \ln \frac{r_4}{r_6} + \dots \right] \quad \dots\dots [10]$$

where r_2, r_4, r_6 are the distances from the sources to the point, and r_1, r_3, r_5 are the distances from the imaginary sinks to the point.

Fig. 3 shows a plot of the strength ratio versus tube spacing for the center pipe of a three-pipe combination at a 2-in. depth of burial in sand. The values for this plot were obtained by considering only three pipes and using Equations [8] and [9]. It is noteworthy that this curve will hold theoretically for any source temperature when employing Equations [8] and [9], provided bound-

FIG. 3 STRENGTH RATIO AS FUNCTION OF PIPE SPACING FOR CENTER PIPE OF THREE-PIPE COMBINATION

any conditions are assumed to remain constant. Whether or not the curve will be valid for a wide temperature range in actual practice is a matter of experimental confirmation. In an actual slab where there is a series of tubes, it is obvious that when the pipes are spaced closely, there will be more than two pipes which will affect the temperature potential θ_p , and therefore the strength ratio. In any arrangement of a series of sources, one must take into account the effect of all those sources which influence the potential θ_p , Fig. 1.

It should also be mentioned that the smaller the depth of tube burial and the closer the tube spacing, the greater will be the error introduced by using this method based on line sources and sinks. In using the treatment based on line sources, the assumption was made that the isothermal at a distance r_0 (through point P , Fig. 1), from the source is circular and therefore represents the pipe surface. The isothermal through point P will not remain circular as two sources come close together, or as the distance to the surface becomes small, but will become distorted. The greater the distortion, the greater will be the error introduced.

An illustrated solution of the foregoing treatment is given in Fig. 4. This figure shows a method of using the temperature gradient along the horizontal center line from a single buried tube to obtain the gradient that would occur along the horizontal center line for a three-tube combination. For example, the resulting temperature potential at point P is given by

$$\theta_p = \eta_A \theta_{A_0} + \eta_B \theta_{B_0} + \eta_C \theta_{C_0} \quad [11]$$

where

$$\eta_A = \frac{\theta_0}{\theta_A}$$

and

$$\eta_B = \eta_C = \frac{\theta_0}{\theta_B} = \frac{\theta_0}{\theta_C}$$

Temperature potentials θ_0 , θ_p , θ_A , θ_B , θ_C , θ_{A_0} , θ_{B_0} , and θ_{C_0} are shown in Fig. 4. The resulting gradient along the horizontal center line connecting the three tubes is obtained by adding the potentials at a number of points as just shown. In this way, the temperature-distribution pattern of a single tube is used to obtain the temperature pattern of a combination of tubes for any particular tube spacing. If the experimental temperature gradients from the single tube are used in applying the illustrated superposition method, the results should be more accurate than the results obtained from an analytical solution where boundary conditions are approximated.

EXPERIMENTAL EQUIPMENT AND PROCEDURE

The experimental phase of this work consisted in obtaining data on the temperature-distribution patterns around single and multiple buried tubes, in order that the proposed superposition method could be checked. Temperature patterns were obtained for the following conditions:

- 1 Single tube as the only heat source in the solid.
- 2 The tube combined with either one or two other heat sources (tubes at the same temperature at a distance of 6 in. from centers).

FIG. 4 ILLUSTRATED APPLICATION OF SUPERPOSITION METHOD FOR CASE OF THREE HEAT SOURCES

FIG. 5 THERMOCOUPLE ARRANGEMENT AT CENTER CROSS SECTION OF SLAB

FIG. 6 EXPERIMENTAL EQUIPMENT SHOWING ARRANGEMENT OF THERMOCOUPLES

FIG. 7 EXPERIMENTAL EQUIPMENT SHOWING SLAB UNDER TEST

3 In both of these cases, three depths of burial were used, namely, $\frac{1}{2}$ in., 1 in., and 2 in.

The experimental equipment used to obtain the temperature pattern around the buried tubes consisted of a box containing three $\frac{3}{8}$ -in.-OD copper tubes buried in sand at various depths. Copper-constantan thermocouples were installed in a radial pattern around the middle tube at the center cross section of the slab. Fig. 5 shows the typical arrangement of the thermocouple

for the 1-in. depth of tube burial. The thermocouples indicating the tube temperature were soldered on top of each tube. All thermocouple leads were brought out parallel to the tubes. Fig. 6 shows the box containing the tubes and thermocouples before the sand was poured. The thermocouple leads were held in place by four $\frac{1}{8}$ -in. plywood boards which had small holes drilled to accommodate the leads, Fig. 6. Dry sand which had been sifted through a 16-mesh screen was poured into the center section,

care being taken to prevent movement of the thermocouples. The sand was not packed, but merely allowed to run freely into the box. Expanded vermiculite (loose particle size) was poured into the two end sections on each side of the sand to provide insulation to reduce the heat flow in the direction parallel to the pipes. Thus the heat flow in the sand slab was essentially two-dimensional. Fig. 7 shows the assembled slab with the copper tubes buried at a depth of 1 in. Additional thermocouples outside the box were placed as follows: One shielded thermocouple 2 in. above the sand over the center pipe to record the air temperature; two thermocouples between the box and the floor, one of which was above and the other below the blanket-type insulation which was placed between the box and the floor.

The thermocouple emf was measured by a semiprecision portable potentiometer which could be read accurately to within 0.2 deg. During all tests the water temperature in the tubes and the ambient room air temperature were maintained within approximately 1 deg.

Three tests were run for each depth of tube burial to determine the temperature-distribution pattern around the center tube. The first test was run with the water directed through the center tube only. Immediately after the temperatures were recorded for the first test, the valve on one of the outside tubes was opened and the water was passed through two tubes for the second test. Water was passed through all three tubes for the third test. During the equilibrium period, thermocouple readings were recorded along the horizontal center line. When the temperatures at points along this line ceased to change with time, it was assumed that steady-state conditions existed. The water temperature was maintained constant throughout the three tests for each depth of tube burial. The air temperature was also constant throughout the progress of the tests. After temperatures throughout the cross section of the box, and the air and floor temperatures were recorded, an exploring thermocouple was used to obtain the surface temperature of the surrounding walls and ceiling.

DISCUSSION OF RESULTS AND CONCLUSIONS

The results are summarized in Table 1, and Figs. 8, 9, and 10, which show a comparison between experimental temperatures, the temperatures obtained by using the superposition method and

temperatures computed by the Equation [1] proposed by Vanderweil.

In applying the superposition method, the temperature potential at any point in the slab was taken as the difference between the temperature at a given point and the "sink" (ambient) temperature. The true sink temperature would be difficult to obtain as it would depend on the following temperatures:

- 1 The true mean radiant temperature of the slab surface, which would be a function of the shape factor of the slab with respect to each of the surrounding room walls.
- 2 The room air temperature.
- 3 The temperature of the floor under the test box.

The true sink temperature would be a weighted average of the foregoing temperatures, proportioned according to the per cent of heat dissipated from the test box by radiation, convection, and conduction (through the bottom). A simplifying assumption was made in applying the superposition method by considering the sink temperature equal to either the air temperature or the average of the air temperature and surrounding surface temperatures, which in most cases would differ from the true sink temperature by less than 2 or 3 deg F, using the air temperature alone as the sink temperature might cause an appreciable error in some cases. Table 1 shows a comparison of point temperatures obtained by the superposition method in which both the air temperature and the average of the air and surrounding surfaces were used as the sink temperature.

The superposition-point temperatures are also compared with experimental values and point temperatures calculated using Vanderweil's theoretical equation (see Table 1). Vanderweil recommends that in applying his equation for calculating the minimum panel-surface temperature (midway between tubes) that the equivalent depth of the tube burial be multiplied by an experimentally determined correction factor; this correction factor would compensate for the increase in the equivalent boundary layer at that point due to a smaller temperature difference between the air and panel surface. In computing the temperatures shown in Table 1, this correction factor was not used, which might account partly for the deviation of surface temperatures calculated by this method compared with the experimental data.

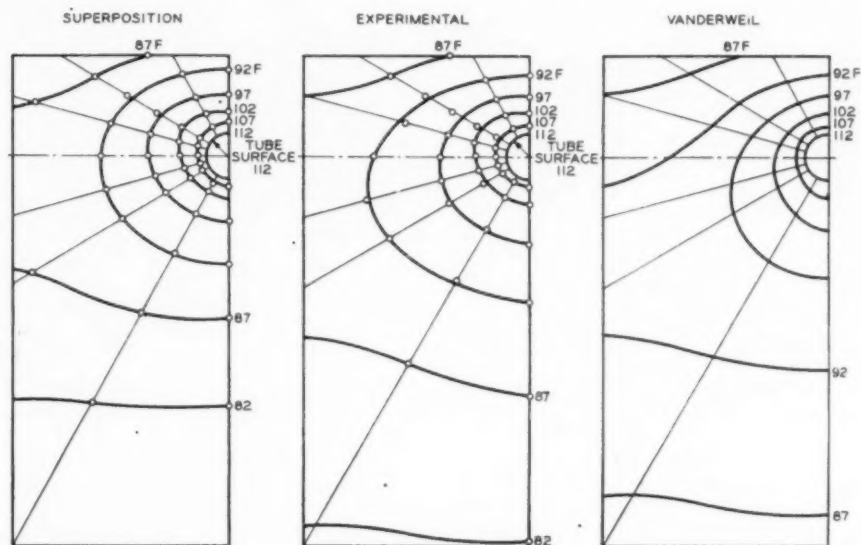

FIG. 9 COMPARISON OF ISOTHERMAL PATTERNS OBTAINED FROM EXPERIMENTAL, SUPERPOSITION, AND VANDERWEIL METHODS

FIG. 8 COMPARISON OF EXPERIMENTAL GRADIENTS WITH GRADIENTS OBTAINED BY SUPERPOSITION METHOD AND VANDERWEIL EQUATION

Fig. 8 shows a comparison of the experimental temperature gradients along the surface and horizontal center line between tubes, compared with those obtained by the superposition and the Vanderweil method. The average of the air and surrounding surface temperatures was taken as the sink temperature.

Fig. 9 shows a comparison of the temperature-distribution patterns around the center tube of a three-tube arrangement obtained by the experimental, superposition, and Vanderweil methods. The average of the ambient air and surrounding surface temperatures was taken as the sink temperature for the superposition method.

Fig. 10 shows the same isothermal patterns that are shown in Fig. 9, superimposed on each other so as to give a more direct comparison. It is seen that the agreement is very good between the three methods above the horizontal center line of the tube. Below the horizontal center line, the experimental isotherms fall about half way between those determined by the superposition and Vanderweil methods. The deviation of the superposition method from the experimental might be partly explained by experimental difficulties. The floor temperature under the test box could not be controlled and varied as much as 4 or 5 deg F. Therefore the true sink temperature for the experimental case,

FIG. 10 SUPERIMPOSED COMPARISON OF ISOTHERMAL PATTERNS OBTAINED FROM EXPERIMENTAL, SUPERPOSITION, AND VANDERWEIL METHODS

and the sink temperature used in applying the method were different. This caused a change in temperature potentials for points below the tube, and thus resulted in a deviation between the experimental and superposition isothermal patterns.

Results presented here are for the 1-in. depth of tube burial only. For the $\frac{1}{2}$ -in. and 2-in. depths of burial the results of the superposition and Vanderweil methods deviated from the experi-

mental results by about the same amount as for the case of the 1-in. depth of burial.

The results obtained here by using the superposition method cannot be taken as conclusive validation of this method, even though there is reasonably good agreement with the experimental data. It should be remembered that only one tube spacing (6 in.), one type of material (sand), and one value of temperature difference between water in the tube and air (approximately 37 deg F) were investigated. On the basis of the results for the particular case considered, it can be concluded, however, that both the superposition and the Vanderweil methods may be used to give a good approximation of the temperature-distribution pattern around one of a series of embedded tubes.

Equation [7], which has been derived to give the strength ratio, may have application in many heat-transfer problems such as the spacing of tubes in a heating or cooling panel, the arrangement of tubes for ground coils used in conjunction with the "heat-pump" and many similar applications.

ACKNOWLEDGMENTS

The author wishes to express his sincere thanks to Dr. Y. S. Touloukian, Prof. F. W. Hutchinson, and Dr. Max Jakob for their encouragement and helpful suggestions throughout the course of this work.

Discussion

Y. S. TOULOUKIAN.¹ The author should be commended for his interesting and useful contribution. To the best of the writer's knowledge, this is the first time that the well-known theory of superposition has been adapted to the field of heat transfer, using a simple technique. It is thought that this semianalytical, semi-empirical method would be inherently better than a purely analytical approach on the equivalent convection radiation coefficient, because the author makes use of the experimental gradient for a single tube as the basis of his solution to obtain the surface temperature distribution for a series of tubes. This experimental gradient does take into account the exact influence of $(h_c + h_r)$.

Of course it should be kept in mind that this method does have limitations as set forth in the paper.

Further experimental work of broader scope would be a more conclusive check on the method presented in this paper.

The Coal-Hydrogenation Demonstration Plant at Louisiana, Mo.

By J. A. MARKOVITS,¹ LOUISIANA, MO.

The 200 to 300-bbl per day capacity demonstration plant hydrogenates coal at 700 atm pressure in two stages. First, coal paste is liquefied with finely divided iron catalyst at 525 atm hydrogen partial pressure, then the middle oil distillate is further hydrogenated in the vapor phase on fixed catalyst beds. The hydrogen is made by catalytic reforming of natural gas with steam.

INTRODUCTION

BACKGROUND information on the national liquid-fuel situation and status of the American synthetic-fuel research has already been presented by Dr. Schroeder.² The report mentioned Bureau of Mines demonstration-plant activities at Louisiana, Mo. Two plants were erected adjacent to the government-owned synthetic-ammonia plant: A 200 to 300-bbl per day capacity coal-hydrogenation plant and an 80 to 100-bbl per day capacity gas-synthesis plant.

The gas-synthesis plant will not be discussed in this presentation. For general orientation it may be mentioned that, when completed, it will produce synthetic fuels by the Fischer-Tropsch synthesis method from hydrogen and carbon-monoxide mixtures derived from gasification of pulverized coal with oxygen and superheated steam. Major component parts of this installation are the 1-ton per hr capacity Linde-Frankl oxygen plant, the pulverized-coal gasification plant, the gas-purification plant, the Fischer-Tropsch synthesis plant, and the product-recovery unit or refinery. The total plant construction is nearing completion, but the component parts were started up as soon as progress of the construction made it possible. The oxygen plant started producing 98 per cent pure tonnage oxygen as early as January, 1949, and pulverized coal was gasified in the plant with oxygen and superheated steam in May. Operation of the integrated plant is anticipated in 1950.

The coal-hydrogenation-plant construction was completed in January, 1949, but partial test runs were under way by November, 1948. The plant produced the first synthetic liquid fuels from lignite derivatives in April, 1949. In this presentation the process will be described as it is practiced in the demonstration plant. Details of conventional procedures will have to be omitted for brevity.

The plant was designed and built by the Bechtel Corporation of San Francisco, Calif., under technical direction and supervision of the Bureau of Mines. In the plant, 10,000 psi operating pressures are combined with temperatures up to 1000 F, and the materials to be processed at these conditions range from gases to mixtures of viscous liquids containing high percentages of abrasive solid particles. These service conditions presented many un-

usual engineering problems. Coal has been hydrogenated in Germany on a rather extensive scale for the past 20 years, but the process was new in the United States. Few items were commercially available for the chosen process. Where there was a choice between importing equipment from Germany or building it here, the latter was done. It was the hard way, but it was considered desirable to acquire design "know-how" and to give American manufacturers an idea of the basic requirements for the design of future commercial-size plants. Within the limitations of the project the equipment was chosen and sized so that the results of operations would be representative of those expected in modern full-scale hydrogenation plants.

THE PROCESS

Coal and petroleum differ in appearance but are similar in chemical composition. The main constituents of both are carbon and hydrogen, although the carbon:hydrogen ratio, the arrangement of the atoms in the molecule, and the molecular weights are different. In addition, coal contains more oxygen, nitrogen, sulphur, and mineral impurities or ash. To convert coal into gasoline the carbon and hydrogen atoms have to be rearranged, the hydrogen:carbon ratio must be approximately doubled, and the ash has to be removed.

In the demonstration plant all this is done at the 700-atm pressure level and in two stages. In liquid-phase hydrogenation a pulverized coal-oil paste is liquefied with hydrogen at elevated temperatures in the presence of a finely divided catalyst, such as iron oxide. In the vapor phase the middle-oil cut of the liquefied coal, which boils below 625 F, is converted into gasoline and by-products with hydrogen over a solid bed of catalyst containing tungsten or molybdenum. Fig. 1 is a simplified flow diagram and shows the two main steps in proper relation to the necessary auxiliary operations.

The raw coal is first crushed to minus $\frac{3}{4}$ -in. size, then pulverized to minus 60 mesh in a ball mill and dried to 1 or 2 per cent moisture content by a gas-fired recirculating drier. The pulverized coal is mixed with a small quantity of catalyst, such as iron oxide or tin oxalate and with heavy oil, previously obtained from the liquid-phase process into a paste, containing approximately 47 per cent solids.

The viscous paste is injected into the paste preheater by steam-driven plunger pumps working at 10,000 psi. The preheater is of modified radiant type, in which the high-pressure tubing is protected by a superheated-steam jacket. Before the paste enters the preheater, a small volume of hydrogen is injected to reduce the viscosity. The mixture is then heated in the first section to about 570 F. At this stage, additional hot hydrogen and recycle heavy oil are added to jump the temperature to the 640 F level, circumventing coal-swelling difficulties that would occur around 600 F. After passing through the remainder of the preheater, the mixture leaves at about 815 F and passes into the first of two converters. For 95 per cent conversion of the coal to liquid and gaseous products, the residence time is approximately 1 hr. The reaction is highly exothermic, and to maintain the reaction temperature at 930 F, cooling hydrogen is added to the converters in controlled amounts at different points.

After the second converter, the reacted products enter the

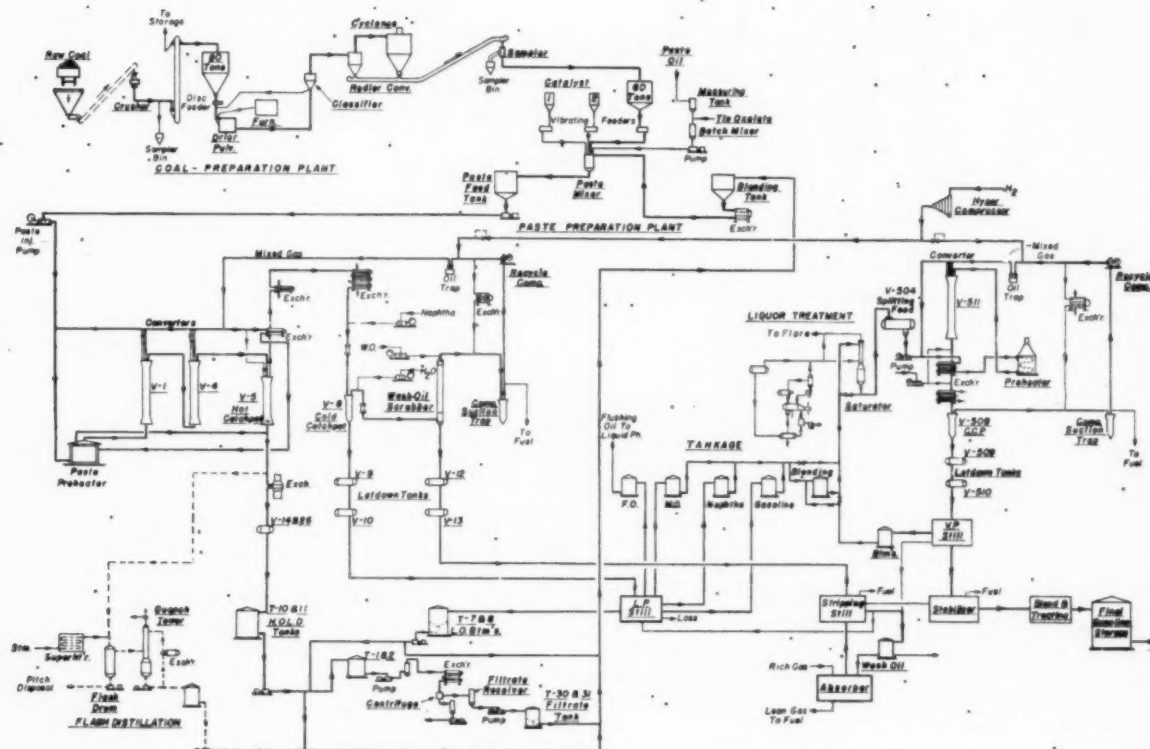

FIG. 1 PROCESS-FLOW DIAGRAM OF COAL-HYDROGENATION DEMONSTRATION PLANT

"hot catchpot," where the hydrogen and light ends separate from the solid-containing heavy-oil fraction. "Letting down" the heavy oil to near atmospheric pressure is the next step. This is extremely difficult, because the hot liquid contains large quantities of absorbed gases and up to 30 per cent of abrasive solids. The heavy-oil letdown valve, therefore, is considered one of the critical pieces of equipment and will be described in detail in a companion paper.

Two methods are provided for removing ash, catalyst, and unreacted coal from the heavy-oil letdown (HOLD). The first is a flash distillation unit (see Fig. 2), consisting mainly of a gas-fired heater for superheating steam to 1100 F, and a flash tower with high-velocity nozzles for instantaneous mixing of the hot steam and HOLD. The resulting mixture is quenched with saturated steam to prevent coking in the flash tower, which is 5 ft diam and 15 ft in height. Residue is withdrawn by steam-driven pumps and injected into a water-spray chamber for quenching. It is expected that the pitch will be hard and suitable for fuel; if not, other methods will be studied for the utilization of this waste product. The vapors from the flash tower pass to a quench tower and are cooled with oil of controlled temperature, to prevent congealing in the vessel. The recovered heavy-oil is used in the pasting-oil cycle.

The alternate method consists of a Bird and a Sharples centrifuge, with facilities for blending and diluting the feed as well as for temperature control on the inlet and jacketed drums and for collecting the filtrate and residue. The filtrate is used in the pasting-oil cycle and the residue burned or otherwise disposed of.

The gases and vapors leaving the top of the hot catchpot are cooled in a heat-exchanger and water-cooler system from about

850 F to 150 F, and the condensed liquid and vapor are separated in the "cold catchpot." The gas from the cold catchpot, containing about 70 per cent hydrogen, is washed with water at full operating pressure for the removal of NH_3 , H_2S , and water-soluble salts and is scrubbed with oil obtained in the liquid-phase distillation unit to separate the light hydrocarbons. After this purification, the hydrogen stream is recycled through the system with fresh make-up hydrogen. The liquid products from the cold catchpot and from the wash-oil scrubber go through let-down systems, where the pressure is reduced in two steps, first to 25 and then to 7 atm, and are then charged to the liquid-phase distillation unit. This two-step letdown facilitates economical separation of the C_1 and C_2 rich tail gases from the liquefied petroleum gases.

The bottoms from the liquid-phase distillation unit join the pasting-oil stream. Gasoline, naphtha, and middle-oil cuts are separated to establish weight relations and to prepare, by blending, after the separation of the washing oil, a feed stock of uniform composition for the vapor-phase hydrogenation. This stock is combined with a nearly equal amount of vapor-phase recycle middle oil and saturated with H_2S or with sulphur for the vapor-phase-hydrogenation step. The addition of some form of sulphur is necessary to preserve the activity of the vapor-phase catalyst.

The vapor-phase injection pumps, working at 10,000 psi, feed the charge, to which hydrogen is added, through a feed-product exchanger and a radiant-type vapor-phase preheater. The stream leaves the preheater at around 850 F completely vaporized. This vapor enters a single converter containing six fixed-catalyst beds. The catalyst is fuller's earth, treated with hydrofluoric acid and impregnated with compounds of zinc, molyb-

denum, chromium, and sulphur. The catalyst is very rugged and at 700 atm performs the triple duty of the former German saturation, splitting, and dehydrogenation operations. The reaction is quite sensitive to temperature variations, and recirculated cooling hydrogen is added at every catalyst bed to keep the temperature between the 912 and 930 F operating limits. After the reaction is balanced, the feed-product exchanger provides most of the heat necessary, and the duty of the preheater becomes negligible.

The products then pass through a cooler and a cold catchpot, where the condensed oil and hydrogen are separated. The hydrogen is returned to the circulating compressors, and the liquid passes through a two-step letdown system to the vapor-phase distillation unit. The primary purpose of this unit is to separate the finished product from the recycle oil. Since conversion in the vapor-phase hydrogenation unit generally varies between 40 and 60 per cent, the distillation unit makes about 40 to 60 per cent bottoms, which are recirculated to the vapor-phase hydrogenation system; the overhead is stabilized to a 10-lb RVP gasoline, washed with caustic and water, and sent to final storage. Tail gases pass through an absorber before being used for fuel. Ammonia, CO_2 , and H_2S liquors are treated with sulphuric acid before going to the sewer, and the recovered H_2S is utilized to saturate the vapor-phase charge.

Make-up hydrogen of about 11 per cent by weight of the moisture- and ash-free coal is furnished from the former Missouri Ordnance Works' natural-gas reformer, scrubber, and compressor system. Here natural gas is cracked with steam at 1700 F, and the resulting H_2 and CO are shifted with more steam at 800 F to H_2 and CO_2 . The mixture is stored in a 300,000-cu-ft gas holder and compressed through three stages of a 7-stage 210,000-cu-ft per hr capacity compressor to 450 psi (see Fig. 3), at which pres-

sure the CO_2 is scrubbed out with water. After the 7th stage, around 11,000 psi, the remaining CO is changed by catalytic reaction into methane and water. The resulting 95 per cent pure hydrogen is ready for injection into the gas-circulating system.

The recirculating compressors shown in Fig. 4 provide the large excess of hydrogen necessary to keep the partial pressure of the system at 525 atm. Approximately 250 standard cu ft of recycle gas is circulated for each gallon of paste. The reaction is highly exothermic, and the circulating gas must be kept cold for temperature control. Failure of the gas-recycle system would result in coking up of the converters, runaway temperatures, and disaster. So important is this function, that the circulating gas is called the "bloodstream of the process." One steam-driven and one motor-driven recycle compressor are operated continuously for each hydrogenation phase at half load, so that in case of failure of any unit, the other would immediately pick up the whole load. The units are single-stage double-acting reciprocating compressors and are designed to maintain a pressure differential of 750 psi with a 450,000 standard cu ft per hr output.

PLANT EQUIPMENT

The facilities required to carry out the operations described can be subdivided into the following groups:

- | | |
|---|------------------------------|
| 1 Coal preparation. | 8 Vapor-phase hydrogenation. |
| 2 Paste preparation. | 9 Vapor-phase distillation |
| 3 Hydrogen manufacture. | 10 Ash removal. |
| 4 Hydrogen compression and purification | 11 Heavy-oil blending. |
| 5 Gas recycle and scrubbing. | 12 Gas recovery. |
| 6 Liquid-phase hydrogenation. | 13 Storage and transfer. |
| 7 Liquid-phase distillation. | 14 Instruments. |
| | 15 Auxiliaries |

FIG. 3 MAKE-UP HYDROGEN COMPRESSOR

FIG. 4 CIRCULATING HYDROGEN COMPRESSORS

Detailed discussion of the foregoing groups will be omitted; and only a few comments will be offered, where necessary, to augment the process description. Thorough analyses of the more difficult coal-hydrogenation-equipment problems are given in companion papers elsewhere in this issue.

The coal-preparation plant was designed and furnished by Roberts & Schaefer Company, Chicago, Ill. It consists of track hopper, plate feeder, scraper conveyer, primary crusher, crushed-coal storage bin, feeder, gas-swept ball mill, gas-fired flue-gas heater, cyclones, fans, and water tumbler. It will pulverize and dry 10 tons per hr to 99 per cent minus 60 mesh, 85 per cent plus 200 mesh, 10 to 2 per cent moisture. Coal washing was eliminated from the original plans but may be added later if necessary.

The paste-preparation unit consists of a pulverized-coal storage bin, weighing feeder, paste mixer, paste storage tank, and facilities for mixing and adding measured quantities of dry or wet catalyst.

Paste is kept above 210 F and is circulated by Moyno pumps past the suction intake of the high-pressure injection pumps.

Although all lines and containers are steam-jacketed, viscosities as high as 1300 centipoises are encountered at this temperature. Coal and paste-preparation plants are shown in Fig. 5.

Hydrogen manufacturing, compression, purification, gas-recycle, and scrubbing facilities were described with the process. The technique employed and equipment used are adaptations of the Hercules Powder Company's 15,000-psi ammonia-synthesis practice. Make-up compressors and recycle-gas circulators were furnished by Ingersoll-Rand. The metallic packings used are quite satisfactory for these services.

The liquid and vapor-phase hydrogenation units are completely new in American industry. The high-pressure vessels, preheaters, exchangers and coolers, tubing, flanging, valves and instrumentation are subjects covered by companion papers.

The severe service conditions of the coal-paste injection pumps place them in the critical category. The paste has a viscosity of 4750 centipoises at the 200 F pumping temperature and 10,300 psig discharge pressure. The pumps are Union Steam Pump Co., 250-lb steam-driven, double-acting, duplex, forged-steel

FIG. 5 COAL-AND-PASTE PREPARATION PLANT

plunger pumps, working at 50 psi suction and 10,300 psi discharge pressure. With 24-in. \times 2 $\frac{1}{2}$ -in. bore and 18-in. stroke, capacity is 25 gpm at 14.6 rpm, and the developed hydraulic horsepower is 150. Application of this time-proved direct pumping method is a promising deviation from the oil-driven hydraulic pumps used previously. Oil, naphtha, and water-injection pumps are similar to the paste-charge pumps, except that the service conditions are not quite so severe. The heavy-oil recycle pump is a steam-driven plunger-type surge pump. It returns hot bottoms to the preheater at 750 F and 10,000 psi pressure. The pump is separated from the hot valve block, and cold, clean flushing oil is the surge medium. An Aldrich-Groff 40-hp motor-driven, vertical-triplex, variable-stroke injection pump is used in flushing-oil service, mainly to determine its adaptability for this type of work. This pump has Teflon packing. The Union Steam pump plunger packings were furnished by Garlock and have four Neoprene-impregnated chevron rings. The 8-in.-deep stuffing box, as well as the steam end, is oil-lubricated. It is felt that a lot will have to be learned by experience about high-pressure seals at the given operating conditions before the problem can be considered solved.

The most troublesome problem of the ash-removal and heavy-oil-blending steps is viscosity and settling of solids. Lines and pumps are steam-jacketed; tanks are equipped with heaters and mixing devices. An elaborate flushing-oil system is provided for these and other parts of the plant to eliminate plugging during shutdown periods.

FIG. 6 COAL-HYDROGENATION DISTILLATION PLANT

FIG. 7 LOOKING SOUTH AT OPEN END OF STALL

The liquid-phase distillation, vapor-phase distillation, gas-recovery, and liquor-treatment units are shown in Fig. 6. Gas recovery consists essentially of an oil absorber to recover enough butane to provide vapor-pressure control in the finished gasoline. No provisions are made for total C_3 , C_4 recovery, and after analyzing the different gas streams most of the LPG will be burned with the fuel gas. The stripper serves both the gas-recovery rich-oil stream and the high-pressure wash-oil scrubber stream. All distillation equipment, such as bubble towers, heating elements, pumps, exchangers, instrumentation, etc., are similar to conventional low-pressure refinery-type installations.

Complete storage, transfer, and loading facilities are provided to hold and handle 30 days' production. Steam, plant water, natural gas, and electricity are provided from the former Missouri Ordnance Works. The total connected power demand of the plant, including hydrogen generation and compression, is less than 4000 kw. Process and power steam requirement is about 100,000 lb per hr. Auxiliary facilities include elaborate high- and low-pressure flushing-oil and inert-gas purging systems, a tail-gas collecting system, and a vent and emergency letdown system with a burning pit. Fig. 7 shows the coal-hydrogenation unit from the converter side.

During plant construction it was found that neither the average American manufacturer nor the construction forces realized fully the severity of the service in a coal-hydrogenation plant. After the design was completed in painstaking detail and reasonably severe specifications were drawn, repeated difficulties were experienced with their enforcement. The importance of careful supervision, inspection, and testing during every step of the fabrication and installation became evident. Standards of excellence, applicable up to 2500-psi service conditions, were not necessarily good enough for 10,000-psi work. In numerous instances flaws in materials and unsatisfactory workmanship were not brought to light until after shop tests, or even after delivery to the job site. One of the companion presentations discusses these problems in detail.

It became evident at an early stage that the demonstration-plant program is really fulfilling its main functions. During the construction and break-in periods, many process and design improvements were developed. In addition, manufacturers gained considerable knowledge in high-pressure design and fabrication methods—a long step toward preparing them for building full-scale plant equipment.

OPERATION OF AN INTEGRATED PLANT

The second phase of the work is under way. It is the demonstration of the operation of an integrated plant, producing synthetic liquid fuels from coal. During this period, operating data are collected, analyzed, and interpreted to determine the effects of operating variables upon the processes and products. This will point the way to further improvements and refinements. More detailed studies will then be made of the economics of the process to determine the cost of products and the investment required for commercial-scale operations.

Finally, engineers and operators are being trained in the required skills of the new industry, and reports will be written for the purpose of disseminating all the technical and economic information developed in the demonstration-plant program. Thus the road toward an economically sound synthetic-fuel industry must lead through the actual construction, operation, and improvement of demonstration and commercial-size plants.

CONCLUSION

In conclusion, it should be mentioned that this paper was prepared in the spring of 1949. Subsequent developments in the coal-hydrogenation demonstration plant will probably be discussed in several publications. It seems advisable though to bring the six papers of this symposium up to date with a short reference to the two completed hydrogenation runs.

The first 10,000-psi vapor-phase hydrogenation run in America was conducted in April, first using a petroleum-crude charging stock, and, thereafter, hydrogenating low-temperature lignite tar oil, mainly into gasoline and Diesel fuel. The actual hydrogenation period lasted 9 days. At the May dedication of the demonstration plants, part of the Diesel oil produced was used on a 200-mile trial run in a Diesel-electric locomotive hauling a loaded 8-car passenger train from St. Louis to Louisiana and back. Since May all plant passenger autos, trucks and cranes, altogether 55 vehicles, have been operated on synthetic gasoline made in this operation.

During the summer all equipment was tested and prepared for the next operation.

The first liquid-phase hydrogenation break-in run was started on October 12, 1949, and terminated on December 2. High-temperature coal-tar oil was first circulated through the system at reduced temperatures, then hydrogenated. On November 25,

a paste was introduced containing 25 per cent of Rock Springs, Wyoming coal. Hydrogenated products from both charging stocks were nearly identical and consisted mainly of naphtha and middle oil suitable for vapor-phase hydrogenation stock.

Hydrogenation at 700 atm was never before attempted in this

country, and the work was conducted with inexperienced operators in a brand new plant containing untried equipment and experimental instruments; hence, the run was considered highly successful. All objectives of both the vapor- and liquid-phase hydrogenations were achieved.

High-Pressure Vessels in Coal-Hydrogenation Service

By J. T. DONOVAN,¹ M. JOSEPHANS,² AND J. A. MARKOVITS³

The converters have to be built to resist 10,000 psi pressure and 1000 F temperature, complicated by hydrogen attack and H₂S corrosion. The three different designs proposed by American manufacturers are compared, and the vessels accepted for the plant are described in detail. The German spirally wound construction is discussed, and its expected advantages are enumerated.

INTRODUCTION

PRESSURES up to 15,000 psi have been used commercially in the synthesis of anhydrous ammonia and there is evidence of higher pressures applied for limited industrial production of plastics. These ranges, however, are unusual in American industry. Hydrogenation of coal combines working pressures of 10,300 psi with temperatures of 1000 F. The steels used must resist attack by high partial pressures of hydrogen and the corrosive effect of 1 per cent by weight of hydrogen sulphide, besides retaining adequate strength at elevated temperatures.

The 200-bbl per day demonstration plant required reaction vessels of 32 in. ID \times 39 ft 1 1/2 in. length. The vessels were sized to provide adequate residence time, proper space velocity, and complete accessibility upon removal of the top and bottom heads. To utilize a low-alloy steel it was desirable to keep the shell temperature as low as 500 F. This was accomplished by providing a 3-in.-thick asbestos-cement liner separating the reaction space from the shell.

COMPARISON OF PROPOSED DESIGNS

Manufacturers of high-pressure vessels proposed three different types of construction for this service, as follows:

- A A laminated wall of perforated carbon-steel plates with a 12 per cent chrome-alloy liner.
- B A two-layer compound cylinder with a perforated carbon-moly jacket over a 3 per cent chrome grooved inner shell.
- C A simple cylinder or solid wall forging of 3 per cent chrome.

Table 1 gives a comparison of the salient features of each design, and Figs. 1, 2, and 3 show the analysis of wall stresses as computed by the Lamé formula, stipulated by the API-ASME Code for vessels having wall thickness greater than 10 per cent of the inside diameter.

The laminated construction had many points in its favor, including the low-cost carbon steel, the close control of the wall material (insuring homogeneous construction), elimination of waste inherent in forging operations, and uniform stress distribution through the entire wall as shown in Fig. 1. On the other hand,

the built-up ends, where the solid flange is welded to the laminated wall section, gave certain fabrication difficulties that caused undesirable increase in both weight and cost.

The compound cylinder construction, similar to that used on large-caliber gun barrels, was considered an excellent and time-proven design for operation at high pressure. However, the close machining inherent in this method of fabrication, in addition to the 1/2 in. heavier wall, resulted in the most expensive unit. This design required perforation of the pervious jacket and machining of grooves on the outer surface of the inner cylinder to permit the

FIG. 1 WALL STRESSES OF MULTILAYER CONSTRUCTION

uniform release of the hydrogen, which diffuses through the alloy layer. These operations also contributed to the higher costs.

Referring again to Table 1, it is apparent that the solid-forged construction has the most points in its favor—it is lightest and lowest in cost; it combines the best physical and noncorrosive properties in one material.

FIG. 2 WALL STRESSES OF COMPOUND CYLINDER

FIG. 3 WALL STRESSES OF SOLID FORGING

DEMONSTRATION-PLANT HIGH-PRESSURE VESSELS

The final design of these units furnished by the Midvale Company of Philadelphia, Pa., is as follows:

Liquid-Phase Converters. These vessels, shown in Fig. 4, are alloy-steel forgings, 32 in. ID \times 49 1/2 in. OD \times 39 ft 1 1/2 in. length, face to face of end flanges, with the ends flanged out to 61 in. OD. The heads are flat steel forgings, 21 1/2 in. thick \times 57 in. diam, provided with the necessary openings for the entry of the coal paste and hydrogen, and the exit of the products of reaction. There are no openings in the converter shell. The shell steel has 3 per cent chrome with 0.65 per cent nickel, 0.30 per cent molyb-

FIG. 4 LIQUID-PHASE CONVERTER ASSEMBLY

denum, and 0.25 per cent carbon, an ultimate tensile strength of 100,000 psi, and an elastic limit of 55,000 psi.

Past experience has shown that a minimum of 3 per cent chromium is desirable to resist penetration of hydrogen and the corrosive effect of H_2S at 500 F and 10,000 psi. The other constituents are necessary for adequate strength in an 8 3/4-in-thick converter wall, where the thickness is based on working unit stress of one fourth of the ultimate tensile strength at the shell temperature as required by the API-ASME Code. All vessels were tested hydrostatically to 1 1/2 times the operating pressure.

The converter heads are subjected to more severe temperature conditions; consequently, it was decided to use a slightly higher content of the same alloying elements, with heat-treatment to provide approximately the same physical properties. The head steel is 4 to 6 per cent chrome with 1 to 1.25 per cent nickel, and 0.40 to 0.80 per cent molybdenum. The head studs, of which there are 12 in each head on a 45 1/2-in-diam bolt circle, are 5 3/4 in. diam, of SAE-4340, with an ultimate tensile strength of 120,000 psi and an elastic limit of 90,000 psi. The stud nuts are of SAE-4140, with an ultimate tensile strength of 100,000 psi and an elastic limit of 70,000 psi. The shell proper weighs about 80 tons, each head about 7 1/2 tons, and the assembled converter, with internals, about 105 tons.

In determining the required head thickness the problem was approached by assuming a head thickness of 18 in. and substituting this value in Roarks' formulas⁴ for determining tension stresses in flat bolted cover plates

$$S_t = \frac{3w}{2\pi ml^3} \left[m + (m+1)L_s \frac{a}{r_0} - (m-1) \left(\frac{r_0}{2a} \right)^2 \right]$$

⁴ Roarks' Formulas for Stress and Strain, p. 18S.

where

$$a = 22.75 \text{ in.} = \frac{\text{bolt circle diameter}}{2}$$

$$r_0 = 16.625 \text{ in.} = \frac{\text{gasket contact diameter}}{2}$$

$w = 8,960,000 \text{ lb} = \text{total force on head from internal pressure}$

$t = 18 \text{ in.} = \text{head thickness}$

$m = 3, \text{ reciprocal of Poisson's ratio}$

Then

$$S_t = \frac{3 \times 8,960,000}{2\pi \times 3 \times 324} \left[3 + 4 \left(\frac{L_n}{16.625} \right) - (3 - \nu) \left(\frac{16.625^2}{4 \times 22.75^2} \right) \right]$$

$$S_t = 17,500 \text{ psi (without holes)}$$

This stress was then checked by using the API-ASME Code formula stipulated in paragraph W-316.

In an 18-in.-thick head this gives a value of 19,500 psi (without holes).

The thickness was then analyzed, taking into consideration the weakening effect of the large centrally located hole in the head.

Using formula⁵

$$S_t = \frac{Wk_1}{t^2}$$

where

$S_t = \text{allowable tensile stress at outer edge of hole} = 25,000 \text{ psi}$

$W = \text{total force from internal pressure} = 8,960,000 \text{ lb}$

$k_1 = 1.25 \text{ (derived from graph on ratio of bolt circle to gasket circle radii)}$

then t becomes 21.2 in.

It was decided to use a thickness of 21½ in. owing to possible higher temperatures which might occur on heads, and to reduce the elastic strain which might result in undesirable gasket action.

The bolts were sized in the conventional manner, based on a working load of 8,960,000 lb, which resulted in a working stress for the twelve 5½-in.-diam studs of 30,500 psi, or about one third of the elastic limit.

The asbestos-cement lining for the converter shell is mixed in the proportion of 1:1:1 by volume of granulated asbestos, quick-setting Portland cement and water. The mixture is poured and tamped in sections in the annular space between the shell and the basket. The basket is stainless-steel, ASTM-A240-347, and has a reaction space of about 110 cu ft. This steel was chosen for its good hydrogen and corrosive-gas resistance at temperatures up to 1000 F. The basket is 25½ in. ID with ¼-in.-thick wall, perforated with ⅜-in.-diam holes on 3-in. centers for pressure equalization.

The heads of the converter are insulated on the inside with 12 in. of asbestos cement and are sealed to the flanged ends by annealed SAE-1020 steel gaskets. The self-sealing gasket shown in Fig. 5 is of triangular cross section. The 33.250-in.-ID gasket fits into 0.35-in.-deep grooves in head and shell flange. About 0.002-in. copper plating was added to the polished gasket faces which improved the seal considerably by eliminating the galling of contact surfaces during fluctuation in pressure. The initial seal is created on opposite tips of the gasket by the bolting force. The

gasket becomes deformed after internal pressure is applied as shown by dotted lines in Fig. 5. Sealing actually takes place along faces marked a and b in the cross section. The soft-iron gasket is of small cross section and the internal pressure forces the entire gasket to expand in diameter when the pressure forces the bolted head away from the shell. At this writing it is still controversial how often a gasket can be re-used.

Temperature measurement within the converter is taken through a centrally located 40-ft-long, 2-in.-OD, ⅜-in.-ID seamless-steel pyrometer tube. This tube, held in place by several steel spiders, has a closed bottom and is designed to withstand an

FIG. 5 DELTA GASKET ASSEMBLY

external pressure of 10,300 psi at 1000 F. Inside the tube is a ⅜-in. schedule-40 pipe of ASTM-A276-304 stainless steel, to which are attached six thermocouple elements on 6-ft centers. These elements transmit the temperatures at the various levels to a recording instrument located in the instrument house.

Vapor-Phase Converter. The vapor-phase converter, shown in Fig. 6, is identical with the liquid-phase converter in dimensions and composition of shell and heads. The inner insulation is also the same, except that the liner is ⅜-in. perforated stainless steel. The insulation is recessed for the ⅜-in. cooling hydrogen lines, so that the space inside of the insulation is unobstructed for the insertion and removal of the catalyst basket.

The removable catalyst basket, shown in detail in Fig. 6, is 24 in. ID, 36 ft 4¾ in. long, and made of ⅜-in. ASTM-A240-347 stainless-steel plate. Both top and bottom ends are bell-shaped and bolted to the body of the basket. Pressure equalization between basket and shell is obtained by holes in the top bell. The catalyst space of about 100 cu ft in the basket is subdivided into six compartments by perforated grids covered by a wire screen to support the 10-mm-diam × 10-mm-long pelleted catalyst. The grids are so constructed that they also serve as a gas-distribution chamber for uniform distribution of the hydrogen supplied to the bottom of each grid by separate ⅜-in. supply lines through the top head.

The pyrometer tube is similar to that in the liquid-phase converter, except that inside of the 2-in.-OD pyrometer tube there is a ⅜-in.-diam solid rod which carries 12 thermocouples for measuring the temperature at two points in each of the six catalyst chambers. The pyrometer tube is enclosed in a shielding pipe, permitting removal of the tube without disturbing the catalyst. The shield is closed at the bottom and made of ASTM-A240-347, schedule-160 pipe.

Hot Catchpot. This vessel receives the products of reaction from the liquid-phase converters. The heavy oil is drawn off at the bottom, while gases and vapors leave through the top of the hot catchpot. The general construction and dimensions shown in Fig. 7, as well as the materials of construction, are the same as for

⁵ "Stress and Deformation in Flat Circular Cylinder Heads," by Gilbert Dudley Fish, Trans. ASME, vol. 43, 1921, p. 615, No. 1805.

FIG. 6 VAPOR-PHASE CONVERTER INTERNALS

the liquid-phase converter, except that the shell is 25 ft 5 1/2 in. face to face of end flanges. The liquid inlet pipe extends downward through the top head a distance of 13 ft 6 in. The normal level of the liquid is about 5 ft above the bottom, while the liquid outlet pipe projects upward through the center of the bottom head to a height of 4 ft. To prevent settling of solids and coking at the bottom, a 1/2-in. size perforated, schedule-40 pipe bent to a 23 1/2-in.-diam ring is provided a few inches above the bottom for agitating and cooling the liquid with hydrogen.

Measuring and regulating the liquid level in the hot catchpot is a very important but troublesome operating function; and, in an attempt to make it foolproof, various methods were provided and are expected to work simultaneously. These methods are described in a companion paper on instrumentation.

The temperature of the hot-catchpot contents is observed by pyrometer readings. The pyrometer tube extends upward from the bottom about 2 ft above the normal liquid level. The thermoelements are spaced 12 in. on centers with at least two elements in the vapor space.

Cold Catchpots. Fig. 8 shows an assembly of these vessels. They are 24 in. ID, 37 3/4 in. OD, and 16 ft 11 5/8 in. inside length. They are flanged at the top to 47 in. OD and tapered at the bottom to a 2-in.-diam liquid outlet. The top head is 45 in. OD, and 18 7/8 in. thick, and is provided with product inlet and gas outlet openings. The 2 1/2-in.-diam product inlet pipe extends 2 ft below the head, where it is divided into two 1 1/2-in.-diam pipes, terminating in 3/8-in. x 1 7/8-in. rectangular outlets, discharging downward at 15 F, and tangentially along the inner surface of the shell. This arrangement will provide efficient separation of gases from liquids without foaming. At the elevation of the impinging stream, the vessel is lined with an interchangeable carbon-steel wear cylinder, 2 ft long x 3/8-in. wall thickness. The shell analysis is 2.50 to 3.25 per cent nickel, 0.75 per cent chromium, and 0.30 to 0.40 per cent molybdenum, and has an ultimate tensile strength of 100,000 psi and an elastic limit of 55,000 psi. The heads are carbon steel, and the head studs, nuts, and gaskets are the same as for the converters and the hot catchpot.

Since the normal operating temperatures are low, 150 F for the liquid phase, and 80 F for the vapor phase, the cold catchpots are neither insulated nor lined on the inside. For the same reason,

FIG. 7 HOT-CATCHPOT ASSEMBLY

FIG. 8 COLD CATCHPOTS AND COMPRESSOR SECTION TRAPS

the shell steel contains only enough alloy metals to meet the required physical properties. The normal liquid level in the cold catchpot is 7 ft 8 $\frac{3}{4}$ in. above the bottom outlet flange.

Compressor Suction Traps. These vessels, also shown in Fig. 8, are installed in the recycle gas-compressor suction lines from the cold catchpots, to trap the moisture from the gas before it reaches the compressors. They are identical with the cold catchpots.

Wash-Oil Scrubber. The wash-oil scrubber is installed in the liquid-phase recycle gas-suction line between the cold catchpot and the compressor suction trap. The purpose of the scrubber is to wash out the hydrocarbons and impurities from the gaseous products of hydrogenation in order to maintain the partial pressure of hydrogen in the recycle gas at a minimum of 80 per cent. The scrubber is packed with 1 $\frac{1}{2}$ -in. \times 1 $\frac{1}{2}$ -in. steel Raschig rings.

The design conditions are similar to those for the cold catchpot, 10,300 psi at 120 F. In details of the shell, heads, and closures, materials of construction and general dimensions, the scrubber is identical with the cold catchpot, except that it is much longer, being 41 ft 7 $\frac{1}{4}$ in. over-all. Like the cold catchpot, it is tapered at the bottom from 24 in. ID in the body to a 2-in.-diam bottom outlet. The wash-oil inlet pipe through the top head extends down 6 ft to a perforated-steel distribution plate, below which is a packing space 28 ft 8 in. deep. The steel Raschig-ring packing is supported by a steel grate 3 ft 2 $\frac{3}{4}$ in. above the bottom head flange. The gas-inlet pipe extends up from the bottom to a point just below the packing grate and is surmounted by a serrated bubble cap. The normal liquid level in the scrubber is 4 ft above the packing grate. The liquid level is indicated and controlled in the same manner as in the cold catchpot.

STALL STRUCTURE AND REPAIR PIT

All high-pressure vessels are located within a heavy-walled reinforced-concrete structure 193 ft long, 28 ft wide, and 58 ft high, open on the top and rear. To minimize the danger of possible fires or explosions, the structure is divided into six stalls by 14-in. reinforced-concrete walls. A 130-ton gantry crane with a 70-ft lift and 60-ft span straddles the structure and facilitates handling of the heavy equipment. Fig. 9 shows the gantry crane carrying a converter to the stalls visible in the right background.

The two end compartments of the stalls house the preheaters. Next to the preheater are the hot stalls of each phase, containing the converters, high-temperature exchangers, and hot catchpot. In the center are the two cold stalls with the cold catchpots, coolers, and compressor suction traps. In a full-scale plant it is not considered necessary to enclose the cold vessels and preheaters. The experimental nature of the operation justified this extra precaution in the demonstration plant.

Adjacent to the stall area is a reinforced-concrete repair pit 35 ft deep. This pit facilitates the repair and cleaning of the large vessels by permitting vertical removal of internals.

NEW DEVELOPMENTS IN HIGH-PRESSURE-VESSEL DESIGN

The demonstration-plant high-pressure vessels described were built in accordance with the established practice of forged construction. However, during the initial stages of plant design, consideration was given to layer-vessel design and to the spirally wound vessels (Wickelofen) still in the industrial development stage in Germany. The carbon-steel-plate layer vessels proved to be too heavy and expensive, while the spirally wound vessels were not available from American manufacturers.

Latest investigations indicate that the spirally wound vessels have excellent possibilities in future American full-scale operations. Therefore a detailed description of this method seems to

FIG. 9 PANORAMA OF STALL SHOWING GANTRY CRANE

be pertinent to this paper. The Germans developed this method of pressure-vessel construction shortly before the second world war as a modification to the layer vessel designed and constructed by the A. O. Smith Company of Milwaukee, Wis. Figs. 10, 11, and 12 help to visualize the spirally wound method of construction. The principle of design utilized by this method is the shrinkage of each successive layer of the wound strip upon the layer or core beneath. Shrinkage of the layers is achieved by continuously heating each strip electrically to between 1100 and 1550 F just before winding, followed by cooling to atmospheric temperature after it is pressed onto the underlying layer. The resultant predetermined contraction of the metal strip will set up circumferential prestressing necessary for minimum wall thickness. The intimate interlocking of the wound strips provides the necessary longitudinal strength.

The wound vessel is fabricated essentially as follows: The inner tube, which forms the core, may vary in thickness from $\frac{7}{8}$ in. for 30-in-ID to 1 $\frac{1}{4}$ in. for a 48-in-ID vessel. The inner tube must resist corrosion and hydrogen attack at high temperature and pressure. A 3 per cent chrome steel with 0.2 per cent C, 0.4 per cent Mn, 0.3 per cent Si, and 0.15 per cent V was normally used by the Germans for this purpose. A plate of commercial width is rolled to the desired diameter and butt-welded longitudinally. As many of these cylinders as are necessary for the desired length of the vessel are butt-welded together, and then stress-relieved. Dummy ends of plain carbon steel are welded to the ends of the inner tube. These dummy ends, to which the strip ends are welded, are later cut off when the vessel is finished.

The strip may vary in thickness from $\frac{1}{4}$ in. to $\frac{3}{8}$ in., and the width is usually about 10 times the thickness. It may be of plain carbon steel for the lower pressure and temperature ranges or low-alloy steel for higher temperatures and pressures, depending upon operating conditions or strength of material desired. As

FIG. 10 DETAIL OF WICKELOFEN WRAPPING

shown in Fig. 10, the strip is rolled to a tongue-and-groove profile, preferably three or more grooves in width, so that the upper layer of strip can overlap by at least one third its width and still interlock amply for axial strength.

The wrapping lathe can be the same type used for machining solid wall vessels, Fig. 12. The tool carriage can be altered to run on a special track and accommodate a reel of strip, the strip heating and cooling equipment, and a profiled back-up roller. The strips, as received in mill lengths, are butt-welded end to end to a length required to wind a complete layer in one run.

The inner tube with its dummy ends is set on the lathe, and cooling water is turned on inside the tube. Spiral grooves are then cut into the outside face of the tube to match the tongues on the strip, at a pitch equal to the width of the strip, plus a slight clearance.

Before wrapping is started the end of the strip is welded to the dummy end of the inner tube at an angle corresponding to the pitch. The strip passes between guide rollers and is pressed against the vessel by two 6-in-diam profiled rollers diametrically opposite each other, to prevent distortion of the tube. The load on these rollers is about 1 ton. The guide rollers act as the connection for the electric current, which heats the strip as it unwinds from the reel onto the vessel. The power required to heat the strip to between 1100 and 1550 F is furnished at 30 to 40 volts and 4000 to 6000 amp.

After passing under the profiled roller, the strip is quenched by compressed-air jets and about five or six turns later by cold-water jets. The speed of wrapping is about 15 fpm.

After the first layer of strip is completely wrapped, the end is welded to the dummy end of the inner tube and the carriage returned to the other end of the lathe. The next strip is then welded to the first layer strip (see Fig. 10), so that it will overlap the joints of the underlying layer by one third of the width of the strip. The succeeding strips are then wrapped exactly like the first and second, until the required wall thickness is obtained.

To finish the ends of the vessel a flange is formed by the same wound method, a steel ring is shrunk over the strip ends, and the

FIG. 11 WICKELOFEN FLANGES

FIG. 12 WICKELOFEN WRAPPING LATHE

dummy inner-tube ends are cut off to the proper length Fig. 11. Instead of a wound flange of strips, a solid forged-steel flange may be screwed or shrunk on, if desired. Fig. 13 shows a German Wickelofen of the type described.*

Full-Scale Plant Converter. A layout has been made of a full-scale plant converter employing the spirally wound principle. A sectional sketch with the main dimensions and materials is shown in Fig. 14.

In order to take the best advantage of this type of construction, the wrapping strip steel should have a high yield strength. Also, the yield should not exceed 75 per cent, nor be less than 60

* For further particulars on the construction of the "Wickelofen" refer to "Engineering in Hydrogenation Plants in Germany," by J. F. Ellis, published by the British Intelligence Objectives Subcommittee, 32 Bryanston Square, London, W.1., or the office of Technical Services, U. S. Dept. of Commerce, Washington, D. C.

per cent of the ultimate tensile strength. The elongation should not be lower than 17 per cent. It is believed that a low-chrome vanadium steel similar to SAE 6115 could be heat-treated in the wrapping procedure to secure the desired properties.

In designing the vessel shown in Fig. 15, a steel with 90,000 psi yield strength and about 130,000 psi ultimate tensile strength is used. In arriving at the wall thickness, the strip was stressed to 70,000 psi on the outside layer, resulting in compressive stress on the core tube of similar magnitude, Fig. 15. Twenty-two $\frac{3}{16}$ -in. layers were required over a $1\frac{1}{2}$ -in. inner tube. This resulted in an $8\frac{1}{2}$ -in. wall for the specified 56-in-ID vessel, weighing only 316 tons.

CONCLUSIONS

Many improvements are still possible in high-pressure vessel fabrication, particularly for large diameters required in commercial-scale hydrogenation plants.

The spirally wound construction is especially promising. A brief summary of the advantages claimed follows:

- 1 Economy in corrosion and hydrogen-resistant material, since only the core tube needs these properties.
- 2 The thin strips permit treating and forging operations to penetrate the innermost crystals. Thus the safety factor required for nonhomogeneous solid walls can be reduced.
- 3 The method of construction gives higher stress distribution on the outside layers, causing these to stretch uniformly, and thereby permitting visual inspection of amount of growth.
- 4 Reduction of wall thickness from increased physical properties secured by controlled heating and cooling of strip.
- 5 Material lost in machining is only one sixth of that lost in forging solid-wall vessels.
- 6 Fewer operators are required, and the manufacturing time is reduced to one fifth of that required in forging.
- 7 Wound vessels can be made at the plant-site shop, thus simplifying handling and transportation problems.
- 8 The size of vessels is limited only by the capacity of crane handling equipment in the field.

High-Pressure (10,300 Psi) Piping, Flanged Joints, Fittings, and Valves for Coal-Hydrogenation Service

By J. H. SANDAKER,¹ J. A. MARKOVITS,² AND K. B. BREDTSCHNEIDER³

The high-pressure piping components used in the coal-hydrogenation process are described briefly. Some factors considered in design are given. In addition, a short discourse on future design for commercial-scale plants is included.

INTRODUCTION

THE coal-hydrogenation demonstration plant required large quantities of 10,300-psi piping, flanged joints, fittings, and valves of various types. Service conditions introduce unique problems which have to be considered in the design of these elements. Some of these problems are touched upon briefly and resulting designs are described.

At this time it appears probable that most piping in future coal-hydrogenation plants would be made lighter by the use of higher-strength steels. However, the other piping components are unlikely to be changed radically in design.

PIPING

Design and standardization of the 10,300-psi-working-pressure piping presented numerous problems. In selecting materials and determining wall thicknesses, consideration had to be given to process-flow requirements, prevailing pipe-manufacturing practices, permissible stresses, including creep stresses at high temperature, and the effect of corrosion, erosion, and hydrogen attack. In addition, however, it early became apparent that large unit weights were involved; so that it became imperative to design for minimum weight consistent with safety and reliability.

It was realized that the many theories available to explain the failure of thick-walled cylinders from excessive internal pressure gave widely different results at the 10,000-psi design level. The maximum principal-stress theory, in which the tangential stress alone is considered to be the criterion for failure, proved to be the most suitable choice. The ASA code for pressure piping adopts this theory, and in paragraph 122b

$$tm = \frac{D}{2} \left(1 - \sqrt{\frac{S-P}{S+P}} \right) + C \dots \dots \dots [1]$$

where

²Assistant Chief, Coal-to-Oil Demonstration Branch, Office of Synthetic Liquid Fuels, Bureau of Mines.

³Special Engineer, Koppers Company, Inc., Louisiana, Mo.

Contributed by the Petroleum Division and presented at the Petroleum Mechanical Engineering Conference, Oklahoma City, Okla., October 2-5, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-PET-2.

tm = minimum pipe-wall thickness in inches, excluding manufacturing tolerances,

P = maximum internal service pressure, psig

D = outside diameter, in.

S = allowable stress in material due to internal pressure, at the operating temperature, psi

C = allowance for threading and corrosion, in.

A study of Equation [1] reveals how wall thickness varies with allowable stress. By dropping the constant C and rearranging the equation, it becomes

$$\frac{D}{d} = \sqrt{\frac{S+P}{S-P}}$$

where D/d = theoretical ratio of outside diameter to inside diameter. Plotting D/d against allowable stress for the internal pressure of 10,300 psi, the graph shown in Fig. 1 is obtained. Several significant facts are evident from this curve. As the allowable stress approaches 10,300 psi, the D/d ratio approaches infinity. It is also apparent that at relatively low stress values, small increments cause large decreases in D/d ratio. The rate of decrease diminishes as the allowable stress increases.

Calculated data in Table 1 show an interesting comparison of

OUTSIDE DIA / INSIDE DIA, VS ALLOWABLE STRESS IN PSI FOR INTERNAL PRESSURE OF 10,300 P.S.I.

FIG. 1 GRAPH OF PIPE STRESS VERSUS OD/ID RATIO

wall thicknesses and unit weights for $2\frac{1}{2}$ -in-ID pipe, both with and without manufacturing tolerances, using ASTM-A-106, grade B carbon steel for which the ASA Code for Pressure Piping stipulates an allowable stress of 18,000 psi at 375 F, and alternately API 5L, grade C for which a stress of 22,900 psi is allowed at the same temperature.

TABLE 1 CALCULATED WALL THICKNESS FOR $2\frac{1}{2}$ -IN-ID 10,300-PSI PIPE

Material	Wall thickness excluding mfg. tolerances, in.	Weight lb per ft	Wall thickness including mfg. tolerances, in.	Weight lb per ft
ASTM A-106, grade B	1.25	57	1.875	88
API 5L, grade C	0.95	34	1.169	45

It is clear from the data that there was a distinct advantage in using API 5L for low-temperature service. Another notable fact is that manufacturing tolerances had a big influence in the final weight of the pipe. This was a factor which at the time had to be accepted as a necessary evil. Fig. 2 lists final pipe dimensions arrived at with manufacturing tolerances for seamless piping

DIMENSIONS						ALLOWABLE TOLERANCE	
NOM. SIZE	O.D.	I.D.	B	E	F	ON O.D.	ON WALL THICKNESS

FIG. 2 PIPE STANDARDS

which was to be finished by hot-rolling. After completion of some tubes, manufacturing difficulty necessitated a change to cold-drawing, so that there is some slight deviation from dimensions and tolerances listed.

Fig. 3 shows on the left a Croloy 9M tube obtained by hot-finishing. Note the squareness of the inside circumference. On the right is a well-shaped cold-drawn tube.

Following German precedent, materials for piping were divided into four different classes based upon service, as follows:

- Low temperature, up to 375 F.
- Medium temperature, 376 F to 850 F.
- High temperature, 851 F to 1000 F.
- Miscellaneous applications in which $\frac{3}{16}$ -in-ID \times $\frac{3}{16}$ -in-OD type 304 stainless steel or $\frac{1}{16}$ -in-ID \times $\frac{1}{4}$ -in-OD, chrome-molybdenum steel tubing was used.

FIG. 3 PIPING AND GASKET SECTIONS

About the latter, used for instrument pressure leads, flushing, oil injection, nitrogen injection, hydrogen injection, and sampling lines, little need be said, since this type of tubing is regularly manufactured and can be obtained easily from suppliers.

The materials with their properties for the first three classes are listed in Table 2.

TABLE 2 HIGH-PRESSURE (10,300-PSI) PIPING MATERIALS

Maximum service temperature, deg F	Material	Yield point, psi	Ult. tens. strength, psi	Bhn
Low temperature: 0 to 375 (early design)	B & W MT-8040 equal to API-5L, grade C	45000 min	75000 min	159 min
0 to 375 (later design)	SAE 4130	45000 min	75000 min	180
Medium temperature: 376 to 850	Croloy 9M (Ref. B & W Tech. Bul. 6-D p. 49) HT-31,387 normalized and drawn at 1200 F	82000 min	103100 min	223
High temperature 851 to 1000	AISI Type 316	30000	75000 max attainable	

NOTE: Creep stress for 1 per cent elongation in 10,000 hr is about 22,800 psi.

The change in the low-temperature class to SAE 4130, a low-chromium-molybdenum steel, was made during construction of the plant, primarily for improved weldability.

The dimensions given in Fig. 2 are the same for all materials, for the sake of standardization of tubing, fittings, etc. The dimensions were based on the properties of API 5L, grade C, carbon-steel seamless tubing for which, as has been noted, the allowable stress is 22,900 psi at 375 F. It would appear that a higher design stress could have been used for Croloy 9M; however, at the time it was selected, not enough was known about its behavior at temperatures near 850 F to warrant taking full advantage of its strength. In addition, such procedure would have minimized standardization. It will be noted that the dimensions chosen bring the design stress up close to the creep stress for type 316 Babcock & Wilcox 16-13-3. It was considered more desirable to design on this basis than to exceed the OD/ID ratio of 2, which was about the maximum according to German experience. Thicker walls could be expected to give trouble due to greater likelihood of internal faults and to increased temperature stresses. Temperature changes especially would have a particularly detrimental effect on stainless steel with its high coefficient of expansion and low thermal conductivity. For this reason Croloy 9M, which has better thermal-shock properties, was used in emergency let-down lines where temperature could be momentarily over 1000 F and vary widely.

FLANGED JOINTS

In a good high-pressure flanged connection, the following features are desirable:

1 Tightness must be maintained in spite of pressure and temperature fluctuations and of usual piping stresses imposed by torsion, bending, and vibration.

2 Functioning should not be affected by minor pipe misalignments in construction or by slight surface imperfections either on gaskets or faces.

3 Since it is desirable to keep the weight of the joint low, tightness should be achieved with low bolt loads. The following contribute to this end:

(a) A gasket pressure area as near the inside circumference of the pipe as possible.

(b) A design which provides high unit pressures on the gasket seat with relatively low bolt loads.

(c) At least a partial self-sealing at operating pressure.

4 A sufficient number of bolts should be provided so that failure of one during tightening will not cause the joint to fail completely.

With these considerations in mind, a study was made of several types of flanged joints. Fortunately, data on the lens ring joint used in Germany were available for comparison with conventional types. This was finally chosen as the one having most of the desirable characteristics. Fig. 4 illustrates an assembled connection of this type for low-temperature lines. For comparison, a Bureau of Mines pipe, flange, and lens ring was shown mated with the closest-size German pipe and flange.

I. G. FARBEN END PIPE & FLANGE
BUREAU OF MINES SPECIFICATIONS END PIPE, FLANGE, & LENS GASKET.

FIG. 4 FLANGED-JOINT ASSEMBLY.

Fig. 5 shows the shape and dimensions of low-temperature service lens-ring gaskets, and Fig. 6 shows the dimensions of flanges used. It should be noted that a spherical gasket surface is in contact with conical surfaces on the pipe ends. It is characteristic of a metal-to-metal ball-and-cone joint that, with small bolt load, the contact area is extremely small, though very high gasket unit seating pressures are achieved. The gasket is softer than the pipe and its action under load is both plastic and elastic. Plastic deformation takes place over an almost imperceptible area and seals off against minor imperfections in ma-

chined surfaces. The greatest part of the deformation is elastic and occurs both radially and axially. Both the initial elastic deformation set up before pressure application and the internal pressure itself provide the self-sealing effect under operating conditions.

The ball-and-cone shapes allow the lens to find a seating position in spite of minor pipe misalignments. Though surface finish was specified to be very fine, it has been found that minor scratches and toolmarks do not cause leakage.

In spite of careful piping design, expansion stresses in high-temperature lines tend often to place added bending and torsion

in the flanged connections. For this reason a bellows lens as illustrated in Fig. 7, is used in medium and high-temperature lines. This type of lens ring has still greater self-sealing effect because fluid under pressure enters the annular space in the lens and acts over a greater area. Should the bending moments tend to open mating flanges, the bellows lens tends to open and to follow the seating surfaces on the pipe.

Flanging materials and their physical properties are given in Table 3.

The materials from which lens rings are made have in each application a Brinell number about 30-40 points below the piping materials. This follows German practice and is for the purpose of restricting plastic deformation to the lens rings, which are the

elements most easily replaced. Flanges are made of materials different from tubing to avoid galling of threads.

Some idea of the weight reduction achieved by use of the 10,300-psi lens-type joint can be obtained by comparing the weights of a flange for the 2 1/2-in. nominal-size pipe with the weight of an ASA-2500-lb screwed flange for the same pipe size. Each weighs about 50 lb.

Results of a test⁴ conducted in Germany on a 325-atm (4780-psi) working-pressure joint of this type for a pipe with an inside diameter of 4.73 in. are available. It was found that an initial total bolt load of 75,000 lb was increased to 99,000 lb by application of the design internal pressure corresponding to a total fluid force of 94,500 lb. The joint remained tight, and internal pressure had to be increased to 780 atm before signs of leakage appeared. Obviously, self-sealing took place. It is interesting to note that, at design pressure, the total bolt load exceeded the total fluid load by less than 10 per cent. Conclusions of the test report indicated that, for the joint under test, a bolt load between 1.8 and 2.5 times the total fluid load should be used in practice. The lower limit was set to avoid leakage when normal piping forces are applied, and the upper limit to avoid overstrain of bolts in service.

Lens-ring joints are used throughout except for instrument lines. These have conventional cinch joints.

FITTINGS

Fittings are limited to tees, 90-deg ells, and reducers, and all are forged and bored. Ells are made by bending straight forged and bored pieces. Table 4 gives materials and their physical properties.

TABLE 4 MATERIAL FOR FITTINGS

Service	Material	Ult. tensile strength, psi	Yield point, psi	Bhn
Low temperature 0 to 375 F	SAE 1030	75000	45000	163 min
Medium temperature 376 to 850 F	Type 304 18-8 stainless steel ASTM-A-182 grade F-8	75000	30000	max attainable
High temperature 851 to 1000 F	Type 316 stainless steel ASTM-A-182-44	75000	30000	max attainable

Details and dimensions of all flanged-type tees are given in Fig. 8. Fig. 9 illustrates welding-type ells. Fig. 10 shows a typical 2 1/2-in. high-pressure line with flanges and fittings.

VALVES

In general, shutoff, throttling, check, and relief valves are used. All bodies are forged steel. Table 5 shows materials and physical properties.

FIG. 9 WELDING ELL OF 90 DEG

All valves are angle type, except for a few vertical-lift check valves, which are straight-through type. The smaller sizes of shutoff and throttling valves are direct handwheel-operated and have screwed packing-gland nuts, while larger sizes, 1 1/2 in. and above, have bolted flanged packing glands, and are spur-gear- and handwheel-operated. Valves are so arranged that the pressure will be above the disk when closed.

FIG. 10 FLANGED ELL AND TEE ASSEMBLY

High-pressure drops during opening and closing, even for mild service, are likely to cause severe erosion of disk and seat materials, unless proper precautions are taken in design. For this reason seat and disk are stellite for shutoff valves and kennametal for throttling valves. Because of the brittleness of kennametal, throttling valves cannot be used for shutoff. Provision must be made to avoid tight seating. This has been done either by providing a spring between spindle and removable disk, or by use of stop nuts on the valve spindle to limit the travel. In addition, throttling and shutoff valves must be paired and valve operations arranged so that all throttling is placed on throttling valves, while only shutoff valves are depended upon for tight shutoff.

Seat rings or bonnet closures for all valves are of the self-sealing type. This keeps down the weight of the valve and facilitates disassembly for replacement of valve internals. Valve packing, where used, is seven-ring type-220 durametalllic with nitrallloy base ring and gland.

Fig. 11 shows a section of a typical shutoff valve. In Fig. 12 a gear-operated 2-in. shutoff valve is compared with a 2-in. 150-psi screwed valve.

Throttling valves fall into two classes, depending upon whether service is severe or mild. Severe throttling valves are used where pressure drop would be from 10,300 psi down to about atmospheric pressure and the fluid is a mixture of liquids, gases, and solids consisting of unreacted coal, ash, and catalyst. Fig. 13 illustrates the valve used for such service. Velocities in the nozzle reach 700 to 800 fps. German experience with a similar valve indicated that a maximum service life with the best seat and disk materials available would be about 1 month. Design, therefore, had to be carried out with the object of attaining longest possible service life and of providing for the quickest and safest possible replacement of either valves or their worn elements. To minimize abrasion of the disk the valve was so designed that, with normal flow conditions, it would be fully open and all of the throttling would occur in the nozzle itself. Further, the nozzle was made with a divergent exit of 7 deg in order to prevent cavitation.

The stream leaving the nozzle enters an expansion chamber and impinges against a "target plate" made integral with the lens ring of the flanged joint on the outlet side of the valve. Flow through the plate is by means of a hole drilled eccentrically to the face which has a concave surface of stellite. The purpose of the expansion chamber and target plate is to provide for the dissipation of the energy of depressuring before entry of the fluid into the piping.

To permit rapid replacement of valve seat and disk, the con-

FIG. 11 SHUTOFF-VALVE ASSEMBLY

FIG. 12 2-IN. SHUTOFF-VALVE COMPARED WITH 2-IN. 150-PSI VALVE

struction is such that disassembly and removal of internals can be accomplished from the top without removal of the valve from the line. In the most severe service, three valves are used in parallel, two being controlled automatically and one hand-operated. One of the automatic valves and the hand-operated valve are spares.

FIG. 13 SEVERE THROTTLING VALVE

Each of these valves is so arranged that three stop valves are on the upstream side and one on the downstream side, in order that it may be tightly isolated from the system for either removal or repair.

The mild throttling valve is much simpler in construction. Removable seat and disk cannot be taken out without removing the valve from the line, however. Fig. 14 shows the construction of one of the smaller sizes.

Check valves used are both angle and straight-through types. The angle type illustrated in Fig. 15 is used for gases and liquids free of solids. Both seat and disk are stellite-faced, and the seat is not removable. The disk is integral with the stem, which is spring-loaded sufficiently to keep the disk seated under conditions of no pressure differential. The spring space behind the stem is connected with the pressure space by a drilled hole for pressure equalization.

The straight-through vertical-lift check valve shown in Fig. 16 is used for slurries or liquids containing solids. It functions like a ball check, but the hollow disk is shaped like a small streamlined aerial bomb. Vertical movement is guided by three stellite-faced vanes 120 deg apart. Seat, disk, and vane guides are stellite-

FIG. 14 MILD THROTTLING ANGLE VALVE

FIG. 15 ANGLE CHECK VALVE

faced also, and the seat is removable. This valve must always be installed with the disk and seat downward, and flow must always be upward.

Relief valves are spring-loaded, as shown in Fig. 17. Disk and seat are stellite and the seat is removable. The disk is integral with the stem, which extends through the coiled spring and is guided near the upper and lower ends.

Control valves are diaphragm type and have the same general features as hand operated valves.

Conventional 15,000-psi straight-through needle stop and angle check valves, and 25,000-psi microreregulating valves are used in high-pressure instrument lines.

FUTURE COMMERCIAL SCALE PLANT DESIGN

As it appears now, only minor changes would be made in design of fittings, flanged joints, and most valves for commercial scale

FIG. 16 VERTICAL CHECK VALVE

FIG. 17 RELIEF VALVE

plants. Possibly the severe throttling valve would be replaced by a pressure letdown engine.

The trend in piping, which is expected to reach a maximum size of 10 in. ID will probably be toward use of higher-strength materials in the low and medium temperature ranges, permitting higher design stresses. Possibly ends of pipe would be upset for threading so that the main body will not have excessively thick

walls. The thinner walls would allow manufacture of most of the required sizes by piercing and cold-drawing rather than by forging and boring. From about 6 in. ID to the maximum of 10 in. ID, manufacture undoubtedly would be by forging and boring.

It is expected that design stresses will be of the order of magnitude of 30,000 psi. A 4-in-ID pipe would then have an OD/ID ratio of about 1.53 and weigh about 60 lb per ft. Using the old design, a 4-in-ID pipe would have an OD/ID ratio of 1.88 and weigh about 108 lb per ft.

Further, it may be possible to substitute Croloy 7 or 5 for the Croloy 9M now in use. In addition, it may be desirable to break up the present medium-temperature service range into several

ranges, and to use a different material for each. Studies would have to determine whether such changes would be feasible metallurgically and if they would reduce costs appreciably.

At this time it is doubtful that a material for high-temperature service piping with a creep strength higher than AISI type 316 can be found. Heavier piping for this service will not affect the overall situation appreciably, since it represents only a small percentage of the total high-pressure piping in a coal-hydrogenation plant.

There are several super alloys in the development stage, but to date there is no evidence that any of them can be used successfully for high-temperature service tubing.

Instrumentation for Coal-Hydrogenation Service

By G. L. BRUNO,¹ F. W. GEYER,² AND J. A. MARKOVITS³

The process requirements of measurement and control are described as applied to high-pressure phases of the coal-hydrogenation process. Special emphasis is given to the details of development and application of special instruments.

INTRODUCTION

THE coal-hydrogenation demonstration plant includes nearly all types of instruments found in normal refinery practice. The instrumentation is not typical of that required in a commercial plant, as many measuring devices were installed for experimental purposes to gather operating data and to accommodate changes in operation with various types of coal. The text of this paper covers only high-pressure instrumentation with emphasis given to unusual items, new developments, and adaptations; it is discussed in the order of temperature, pressure, flow, differential pressure, level, and miscellaneous instruments.

Measurement and control in high-pressure services is not new. However, when applied to coal hydrogenation, other factors complicate the problem. In addition to pressures of 700 atm, there are temperatures of 1100 F, high-viscosity erosive liquids containing up to 50 per cent solids, hydrogen, and mixed hydrocarbon vapors, as well as severe pressure drops of as much as 675 atm, and freezing weather.

In German plants, automatic control was not an economic necessity; therefore instrumentation was not highly developed for this process. It was recognized that solution of the many complex instrumentation problems would offer great possibilities for improvement over the German plants and help adapt coal hydrogenation to the economics of the United States.

The necessity for protection against the hazards of the process established the basis of design for the control center. The control house is a reinforced-concrete building, 34 ft X 90 ft, with a solid 12-in. wall on the north or stall side as further protection. Directly outside the wall are located principal control valves and by-pass valves, the handles of which extend through the wall and panel board and are located directly under their respective instruments for manual operation. The instrument board, containing 121 instruments, consists of 30 control panels and 2 annunciator panels, with 18 panels on the north wall and 7 on each wing. The instruments are either pneumatic or electric receivers, eliminating explosive gases or high-pressure liquids from the control room. High-pressure controllers are on the north wall, with miscellaneous recorders and the annunciator system on the wings. High-pressure controls operate either automatically, remote pneumatically, or manually from the center.

TEMPERATURE INSTRUMENTS

The temperatures encountered in the process design range from atmospheric to 1800 F and makes the use of both iron-constantan and chromel-alumel thermocouples desirable. Twenty-gage thermal elements were used throughout the high-pressure system. This size was selected as the optimum possible, when considering thermal response in relation to thermowell ID and wall thickness, life of element, and resistance of the external instrument circuit. The thermowells used consisted of three types, skin, immersion, and vessel.

Skin-type thermocouple assemblies, as shown in Fig. 1, were required in furnaces, vessel shells, and lines containing abrasive solids. The assemblies were insulated to reduce radiation losses.

The immersion-type wells were used in all clean liquids and gas streams. The relationship of pressure to wall thickness presented the principal difficulties in the design of this type well. The design selected, illustrated in Fig. 2, afforded a minimum wall thickness at the junction of the element and incorporated the lens ring or sealing gasket which is the standard joint seal for high-pressure service.

FIG. 1 SKIN-TYPE THERMOCOUPLE ASSEMBLIES

FIG. 2 IMMERSION-TYPE THERMOWELLS

Measurement of temperature in vessels such as converters and hot and cold catchpots was complicated by the requirement that all thermocouples enter either the top or bottom head of the vessel. The well design is identical for all vessels; however, the description of the method used is confined to the vapor-phase converter, which contained the maximum number of couples and presented the added difficulty of fixed beds of catalyst.

Due to the exothermic reaction of the process, it is necessary to introduce cooling hydrogen into the basket of the vapor-phase converter at each of the five removable grids. Hydrogen is mixed with the hot gases in the grid and flows downward through the next lower catalyst bed. A temperature point in the middle of each bed operates a diaphragm valve which controls the quantity of cooling hydrogen to the bed, maintaining the control temperature.

The pyrometer tube, as illustrated in Fig. 3, is encased in a shield which enables the tube to be removed for repairs without the catalyst falling through the grids. The shield, however, introduces a serious time lag owing to the low velocity of the gases in the converter and the devious path of heat transfer.

FIG. 3 VAPOR-PHASE CONVERTER AND PYROMETER TUBE

Due to hydrogen penetration of the pyrometer tube, it was necessary to seal the outlet where the 12 pairs of thermocouple wires leave the vessel. This was done by using a drilled soapstone bushing tapered at both ends. By tightening a follower nut the soapstone crushes around each wire and tightly seals the pressure in the pyrometer tube. To indicate hydrogen penetration by increased pressure, a special fitting was installed in the pyrometer tube above the vessel with a pressure gage and vent valve.

Temperature measurement and control were obtained by using standard electronic strip-chart multipoint recorders, circular-chart recorder controllers, and multipoint, self-balancing, precision indicators with switch cabinets of 48 and 96 points.

Temperature controllers were designed with manual by-pass panels, and it was felt necessary to incorporate full throttling and automatic-reset-type control. Multipoint recorders and controllers were equipped with high-temperature alarms which actuate the annunciator system. All ranges used on these instruments were standard, except one special circular-chart controller for controlling the vapor-phase feed temperature to the converters

by introducing cooling hydrogen to the stream. This instrument is unusual, in that its range is 850 to 900 F—a span and suppression not normally found in potentiometer-type instruments. This was necessary owing to the narrow span in which maximum hydrogenation efficiency is obtained.

PRESSURE INSTRUMENTS

Static pressure measurement was made with conventional alloy-steel Bourdon tubes in ranges to 20,000 psi. These instruments include indicating pressure gages, nonindicating pressure controllers, and indicating pneumatic transmitters.

The indicating gages are 8 in. diam, with safety features such as shatterproof glass and rupture-disk backs. Connections were made by using 1/2-in. straight pipe thread with annealed-copper gaskets as normally found in hydraulic work. Pressure elements installed in liquid services were equipped with a special high-pressure-design pulsation damper as normally required on services from reciprocating pumps. The measurement of static pressures in streams containing abrasive solids required special consideration, and for this purpose a diaphragm or "homogenizer" gage was used with flushing-oil connections to prevent plugging. This gage consists of a liquid-filled Bourdon tube actuated by the flexing of a flat-bulb-type diaphragm.

Nonindicating pressure controllers, ranging to 15,000 psi, were of conventional design, with special differential-cone-type high-pressure connections. As a protection against rupture of Bourdon tubes, excess-flow check valves were installed ahead of each tube. Transmission to recorders and recorder controllers was performed pneumatically by the conventional bellows system. Controllers were of the full-throttling type.

FLOW INSTRUMENTS

Flow measurement was made in streams consisting of hydrogen, vapors, clean liquids, and liquids containing abrasive solids by using a sharp-edged orifice in all cases except cooling hydrogen streams, where the small flow made orifice-plate measurement impractical. Orifice-plate design coefficients had to be established by extrapolation for the 3/4-in. to 2-in-ID special tubing. Additional problems were presented owing to pulsation from reciprocating pumps and compressors and the necessity of using nonstandard pipe taps of 8 diameters upstream and 8 diameters downstream to meet construction requirements of the lens ring joint, the lens gasket of which is incorporated as part of the orifice plate. It is anticipated that experimental data will be collected during operations to modify the preliminary design coefficients. The materials handled also required the use of accessories, such as seal pots, flushing oil and hydrogen purges, and steam tracing of meter legs.

For streams of small volume in the range of 100 cfh at operating conditions, a second type of primary element was used. The design consists of a helical rotor suspended on instrument pivots against jeweled bearings and contained within a high-pressure housing. A small alnico magnet is mounted on the rotor and as it turns, generates an alternating-current voltage in a pair of coils placed in the assembly. These coils are in series and connect to weatherproof terminals. The output from the transmitter is of a few millivolts magnitude, with frequency and amplitude proportional to the rate of turning of the rotor. This alternating-current voltage is fed to the receiving unit. A proposed alternate method for this service was an electric transmission-type rotameter; however, it was felt that a development such as the helical rotor, if proved practical, would be more suitable for the services and would be considerably cheaper.

The receiver for the rotor-type transmitter consists of 0-100 d-c panel-mounted microammeter. As the output of the transmitter is alternating current of a small magnitude, it must be rectified

and measured on a direct-current instrument. This rectification is done by a copper-oxide rectifier circuit and owing to the non-linear characteristics of the rectifier, it is necessary to bias the rectifier with a direct-current voltage to gain linear characteristics. Due to the biased voltage on the rectifier, it is further necessary to provide an opposing bias current on the indicating meter. This biasing current is supplied from a stabilized 6-volt d-c supply common to the 12 rotor installations in the plant.

Orifice-plate differential measurements were made by two types of transmitters. One consisted of a special 200-in. high-pressure mercury-filled manometer with an inductance-type transmitter. The transmitter consists of a soft-iron armature attached to the float and moves up and down in a nonmagnetic tube surrounded by a center-tapped inductance coil. Due to changing differential pressures, the position of the armature varies with respect to the center tap of the inductance coil. This movement changes the relative inductance of the two halves, the over-all inductance remaining constant.

The receivers for the mercury-manometer-type transmitters are a special adaptation of the electronic self-balancing recorder. They contain a transformer supplying 5.0 or 6.3 volt a-c for power to the system, and a self-balancing slide-wire which repositions itself to balance the voltage changes produced by the inductance-type transmitters. In other words, an alternating-current resistance-inductance Wheatstone bridge is formed between the transmitter and receiver. The simplified wiring diagram is shown in Fig. 8. It was necessary to use the more sensitive-type receiver rather than the standard electric-inductance flow receiver, as the changes in inductance produced by the transmitter-armature movement are much smaller than in the standard

FIG. 4 SECTION OF DIFFERENTIAL STRAIN GAGE

FIG. 5 DISPLACEMENT TRANSDUCER ELEMENT

FIG. 6 REVERSE SIDE OF TRANSDUCER

FIG. 7 SIMPLIFIED WIRING DIAGRAM OF STRAIN TRANSMITTER AND RECEIVER

transmitter. This reduction was a result of the heavy wall thickness of the nonmagnetic tube in the transmitter to withstand the higher operating pressures. These receivers are in all cases recording, full-throttling, automatic-reset, pneumatic controllers.

The second type consists of a high-pressure housing containing a measuring diaphragm and a sealing diaphragm between which is located an unbonded strain bridge or displacement transducer element immersed in a silicon liquid and connected to the measuring diaphragm, as shown in Fig. 4.

The displacement transducer element is shown in Fig. 5. It consists of a frame *E* supporting a movable armature *F* by two thin cantilever plates. Four sets of constant filaments, *A*, *B*, *C*, and *D*, are strung under initial tension between the frame and armature. When the armature is displaced longitudinally, two sets of filaments are elongated while two sets are shortened. The elongated filaments increase in resistance, and the shortened filaments decrease. The change in resistance of the filaments is proportional to their change in length. The transducer is so wired that the filaments are connected in a Wheatstone-bridge circuit. The resistance change of the filament alters the electrical balance of the bridge so that an electrical current flows in the output circuit. The reverse side of the transducer is shown in Fig. 6; *G* indicates the cantilever plates which support the armature; *H* is the linkage pin by which movement from the measuring diaphragm is transmitted to the armature; *I* is a stud attached to the armature which limits the movement of the armature to 0.0015 in. in either direction. This stop serves to protect the filaments against mechanical overload. The resistor *K* is a trimmer placed in series with one of the bridge elements. It is adjusted to equalize the resistance of the four elements of the bridge. If the bridge

Fig. 8 SIMPLIFIED WIRING DIAGRAM FOR MERCURY-MANOMETER TRANSMITTER AND RECEIVER

is balanced at zero output before the displacement is applied, the unbalanced electrical output of the bridge bears a linear relationship to the displacement. The complete wiring diagram, including transmitter and receiver, is shown in Fig. 7.

The receivers for the differential strain transmitters are also special, although different adaptations of the electric self-balancing potentiometer. In this case it is an alternating-current potentiometer with both the strain bridge in the transmitter and the slide-wire in the receiver being supplied power from the same transformer located in the receiver. An alternating-current potentiometer-type circuit was chosen because by connecting the four strain elements in a bridge, the largest and most easily measured output could be obtained. The output is in the order of 25 millivolts for full scale deflection of the receiver whereas, had a resistance-measurement-type circuit been used, the total resistance change for full scale deflection would have been very small with the type of unbonded strain gage used. The span and zero adjustments are accomplished by means of a potentiometer rheostat network located in the receiver and shown on the simplified wiring diagram in Fig. 7. These receivers are in all cases circular-chart recorders.

It can be noted from the foregoing description that two different types of transmitters were used for differential flow measurements. Either type could have been used throughout. The mercury-manometer type was chosen for all control applications, as it seemed to offer the best possibility of maintaining its calibration over a long period of time while the strain-element type is known to have a zero calibration shift with time. The strain type was chosen for straight flow recording on the basis that it was cheaper, and that an instrument of this type should be developed.

DIFFERENTIAL-PRESSURE INSTRUMENTS

Most of the differential-pressure measurements in the demonstration plant were made for collecting experimental data on such items as plastic flow of viscous fluids and exchanger fouling factors. Very few data are available, particularly at high pressures, on the plastic flow of viscous fluids such as coal paste with a viscosity of 4750 centipoises at 200 F, and a Reynolds number considerably below the range of laminar flow; and it is therefore hoped that friction factors and empirical formulas may be developed by the differential-pressure data obtained. Differential-pressure measurements are also used as an indication of changes in fouling factors of exchanger equipment due to coke, salt, and hydrates; and for process control of water-injection rates necessary to reduce the scale and salt deposits in the exchanger tubes.

The primary measuring element and transmitter for these measurements is a differential strain gage as previously described in the flow section with modifications to the diaphragms for ranges of 100, 350, 500, and 1000-lb differentials.

The receivers for these measuring elements were an adaptation of a multipoint strip-chart potentiometer recorder. The basic electric circuit for each point was the same as previously described for single-point recorders under flow measurement; however, owing to the inherent difficulties in manufacture of the strain element, the calibration factors for each transmitter were different and required a separate span and zero adjustment for each point recorded. This span-and-zero adjustment for each transmitter was located behind the receiver case.

Automatic control of differential pressure was used in only two cases—the total differential pressure across the hydrogen-recycle compressors in the vapor-phase and the liquid-phase systems. Both systems are closed and operate independently. It was necessary to by-pass part of the recycle hydrogen at a high enough pressure, to be assured at all times of a sufficient pressure differential to force a controlled flow of cooling hydrogen into the converter, while still maintaining a constant flow of process hydrogen and feed to this same converter. To accomplish this, an excess of recycle compressor capacity is maintained at all times at a pressure differential of from 500 to 750 psi. This differential-pressure-recorder controller is the most important single controller in either phase, as enough cooling hydrogen must be available to prevent a runaway condition due to the exothermic reaction. These receivers are pneumatic, full-throttling, automatic-reset, circular-chart-recorder controllers, equipped with manual by-pass panels.

LIQUID-LEVEL INSTRUMENTS

Level measurement and transmission for all high-pressure vessels was accomplished by using 50-in. high-pressure mercury manometers of the type previously described in the section on flow instruments.

The receivers are circular-chart-recording, full-throttling, automatic-reset, pneumatic controllers with manual by-pass panels. The electric circuit for the receivers of the mercury manometers is the same as that used for the manometer-type flow receivers previously described.

The liquid-level measurement and control of the hot catchpot was the most difficult installation and is therefore described in detail. The hot catchpot is a vessel 24 in. ID \times 38 ft high and is used in the process as the hot liquid-vapor separator. The liquid flow to the hot catchpot is intermittent, and the sudden surges must be minimized by efficient control. The heavy-oil bottoms is a liquid containing approximately 35 per cent solids, consisting of unreacted coal, ash, and catalyst, and a high percentage of absorbed gases. From the foregoing description it can be seen that this service presented many problems as to measurement, control, and maintenance; therefore three separate and distinct level systems were employed. Two were of the pneumatic or bubbler-tube type in conjunction with 50-in. mercury manometers, and the third was of the gamma-ray type described later. The pneumatic liquid-level measuring device consists of a mercury manometer connected to tubes entering the top of the vessel. One tube is terminated near the top to measure the static pressure while the other extends into the vessel to a point near the bottom. The liquid head on the second tube produces the differential on the manometer. Hydrogen is introduced into the two manometer leads through two flow recorders in one case and through capillary throttling devices in the other. The arrangement is shown in Fig. 9.

Owing to the severe service conditions of the hot catchpot, it was felt that an additional type of level measurement and transmission should be employed. This is an electronic instrument utilizing gamma radiation which is capable of measuring changes of level through the heavy wall of the vessel without the use of an access opening. The gamma rays are produced as a result of

FIG. 9 HOT-CATCH-POT LEVEL-CONTROL SYSTEM

natural disintegration of radium in a capsule located within the vessel. The number of gamma rays that penetrate a section of the vessel wall are counted and averaged by a suitable Geiger counter amplifier-integrator circuit, which supplies an output of 0-50 millivolts d c. The intensity of the radiation from the radium source varies with the distance from the source to the counter and with the densities of various materials intervening. The counter is located about 2 ft higher on the outside of the vessel than the radium sources on the inside; therefore, as the liquid rises above the source, the radiation received at the counter is progressively reduced by this intervention of a material of a higher density. The reduction of intensity continues until the liquid level is directly opposite the counter producing a 2-ft operating range.⁴ The electric circuit of the receiver is a conventional self-balancing potentiometer with a range of 0-50 millivolts d c.

The manometer transmitters were wired through a switch on the control panel so that either of the two transmitters could be used on a common receiver controller. The output control air of this receiver was manifolded with that of the gamma-ray receiver controller so that either could be used to control the level in the hot catchpot. This controlled air operates either of the two diaphragm control valves of the severe throttling type, which remove the heavy-oil bottoms from the hot catchpot. A dual valve installation was required owing to the severe erosion caused by the 675-atm pressure drop of the material handled.

Special designed 15,000-psi test gage glasses also were installed on each of the vessels for manual operation and setting of control points.

MISCELLANEOUS EQUIPMENT

Two other types of instruments deserve mention: The thermal-conductivity hydrogen-analyzer recorders, and the Ranarex specific-gravity recorders, which are used as a check on the composition of the gas streams in both the liquid and vapor phase. The instruments are of conventional design. The continuous samples to these instruments were taken from the hydrogen re-

⁴ For further information on the type 79D1 Gagetron refer to the Engineering Laboratories, Inc., Tulsa, Okla.

cycle lines through 1-mm capillary tubing which was used to partly reduce the pressure and to reduce line volume to increase speed of response of the analyzers. The final high-pressure drop was taken across double manual throttling valves into a 10-in. WC bubbler, with part of the sample vented to atmosphere and the balance going to the hydrogen-analyzing cell and the gravimeter.

Instrument piping consisted of $\frac{3}{16}$ -in-ID \times $\frac{3}{16}$ -in-OD type 304 stainless-steel tubing, tees, connectors, and valves. Connections were made by use of a differential cone seal, as shown in Fig. 10. The connections were kept to a minimum by use of bends wherever possible.

The construction details of the diaphragm-control-valve bodies are covered in a companion paper on valves and fittings; however, some additional description covering the control operations is required. The valves are equipped with giant top works or diaphragm with 2-in. travel of the diaphragm through a linkage to give $\frac{3}{8}$ -in. travel of the inner valve. To insure ample power and accurate positioning of the inner valve, all control valves are equipped with valve positioners set for the $\frac{3}{8}$ -in. travel. The

FIG. 10 INSTRUMENT-PIPING CONNECTIONS

port sizes range from $\frac{1}{8}$ in. to $\frac{1}{2}$ in. diam, and the plugs are characterized.

An elaborate annunciator system was installed with a normal amber light and an abnormal red light for each alarm circuit. A common howler with a reset button was used. The common-howler reset button will silence the howler for that circuit which has become abnormal, leaving the red light on and clearing the howler for operation from one of the other alarm circuits. The alarm circuits are used for high skin temperatures, thermocouple burnouts, high and low levels, low steam pressure, and low coal-paste pressure.

CONCLUSION

The special instruments described were developed primarily for

FIG. 11 INTERIOR OF HIGH-PRESSURE CONTROL HOUSE—LIQUID-PHASE INSTRUMENTS

FIG. 12 INTERIOR OF HIGH-PRESSURE CONTROL HOUSE—VAPOR-PHASE INSTRUMENTS

the project through the splendid co-operation of interested manufacturers. The design of the project occurred during a period of peak demand for standard equipment; and it was therefore difficult to find suppliers to produce the equipment. Presentation of ideas to numerous manufacturers, even though they were not interested at the time, has now resulted in the development of some new equipment for high-pressure services. The instruments now in use represent the best that it was possible to develop and obtain but are by no means considered the only or final solution

to the problem. It is hoped that from operating experience and continued co-operation with manufacturers, improvements and new developments may be obtained that will be applicable not only to the coal-hydrogenation process but to any future processes of comparable services. The brief operating experience obtained to date indicates that some modifications and redesign will be required; and, after further and more conclusive information is obtained, it is hoped that additional papers will be written on the subject.

Metallurgical and Fabrication Considerations in the Coal-Hydrogenation Demonstration-Plant Construction

By B. H. LEONARD, JR.,¹ G. D. GARDNER,² AND J. A. MARKOVITS³

Special equipment, special steels, and heavy wall thicknesses were required to handle hydrogen and abrasive pastes at the high pressures and temperatures of coal hydrogenation. Some metallurgical and fabrication problems pertaining to this specialized process are discussed herein.

INTRODUCTION

COMPANION papers presented in this issue describe the coal-hydrogenation plant. An attempt will be made in this paper to show why certain materials were used and to point out some of the fabrication difficulties that were experienced. This discussion is necessarily limited to materials and equipment used for high pressures.

The primary consideration in the choice of materials for various services is the effect of hydrogen at different temperatures. From German and English experience in the hydrogenation field,⁴ it was learned that carbon steels resisted hydrogen attack at a pressure of 10,300 psig up to a temperature of 375 F. Chromium steels in excess of approximately 6 per cent Cr were found to be hydrogen-resistant at higher temperatures.⁵ At these higher temperatures, however, creep strength must also be considered. Above 800 F, straight chromium steels do not have high enough creep strength for the service conditions. These factors led to the establishment of three temperature classifications: 0 to 375 F for carbon steel, 376 to 850 F for intermediate chromium steel, and 851 to 1000 F for chromium-nickel stainless steel.

PIPING MATERIALS

To obtain materials suitable for high temperatures and high pressures, it was necessary to accept some undesirable features; one of these, common to all the metals, was hot-shortness. Seamless tubing was used throughout, with an approximate ID:OD ratio of 1:2. Because of the thick wall involved, difficulty was

experienced in maintaining uniform temperatures throughout the metal, and it was possible for part of the wall to be in the hot-short range at some time during the forming operation.

Low Temperature. The service conditions in the low-temperature range closely simulate those found in normal refinery practice, except for the higher pressures. Hydrogen attack on carbon steel in this temperature range is not evident. Therefore the piping specifications were established in compliance with the ASME Pressure-Piping Code, and specifically with the API 5L, grade C, classification.⁶ This specification requires a minimum yield value of 45,000 psi, and specifies a maximum allowable stress of 22,900 psi at 375 F. The most readily available material conforming to these specifications and adaptable to seamless piercing operations was MT-1040. Normal production of seamless tubing from this material employs a hot-roll finish. Due to the extremely heavy tube wall required, excessive ovality or squareness resulted from this procedure as shown in Fig. 1. Although minimum wall-thickness requirements were met, this

FIG. 1 SQUARED ID OF HOT-ROLLED MT-1040 STEEL TUBE

squareness was undesirable for the following reasons: (1) Tubes of nonsymmetrical cross section will develop undeterminable stress concentrations due to internal pressure; (2) indeterminate problems would result in the calculation of bending and shear stress caused by thermal expansion, pipe supports, and anchors; (3) starting points for corrosive and erosive action, sedimentation and coke formation would be established—especially at points where the squared ID of the tubing meets the round ID of the fittings; (4) proper fluid flow and heat transmission would be impaired; (5) systematic safety inspection of irregular tubes would be impossible.

To eliminate squareness and give a satisfactory finish to the

⁶ ASME Code for Pressure Piping, 1942.

tubes required either boring or cold-drawing. The less expensive solution of cold-drawing was chosen. As a final step, the tubes were given a normalizing treatment for adjustment of mechanical properties.

One of the inherent properties of this steel is a hot-short range from 1400 to 1600 F. Forming should be done in a range of 1800 to 2000 F, and in no case should this material be cold-bent. Some of the tubing was found to have cracks, and it is believed that these cracks were caused by forming at too low a temperature, or in the hot-short range. A typical defect is shown in Fig. 2.

Fig. 2 HOT-SHORT CRACK IN MT-1040 STEEL TUBE

Intermediate Temperature. For the intermediate-temperature service, a steel with a chromium content exceeding 6 per cent was needed to resist hydrogen attack. Standardization of piping was based upon the maximum allowable stress of the low-temperature steel; 22,900 psi at 375 F. A study was made to find a material which at 850 F would have approximately this same allowable stress, and also have enough chromium to resist hydrogen attack. A stronger material would not have been economically sound; conversely, standardization would not have been possible without a material at least this strong. The most readily available material that could be heat-treated to give suitable mechanical properties and contained enough chromium to resist hydrogen was a 9 per cent chromium-molybdenum steel.

This material was found to have the same tendency to square during the customary hot-finishing operation as had been experienced on the low-temperature steel. It was necessary, therefore, to cold-draw this material also. For increased resistance to hydrogen penetration and to obtain required mechanical properties at working temperature, the chromium-molybdenum steel was normalized and drawn at 1200 F. The mechanical properties of this material could be expected to remain stable in operation because of the spread between the operating and draw temperatures. In tests on samples for 1000 hr at 800 and 900 F, only a minor loss could be found⁷ in mechanical strength at room temperature or 900 F.

For the extreme deformation required in the piercing operation, 9 per cent chromium-molybdenum steel should be heated to working range of 2000 to 2250 F. Within the range of 1500 to 1800 F this metal is hot-short, and deformation may lead to cracking at the points of maximum deformation. Because of the air-hardening characteristic of this material, rapid cooling

from above 1400 F could also produce cracks or checks. It is believed that the cracks found on some tubes of this material were caused by working in the hot-short range, Fig. 3.

Fig. 3 HOT-SHORT CRACKS IN 9 PER CENT CHROMIUM-MOLYBDENUM STEEL TUBE

High Temperature. The high-temperature requirements were the most difficult to meet. The material had to resist hydrogen attack and have high creep strength. Again, for standardization purposes, it was necessary to find a material with a creep strength at 1000 F, close to the maximum allowable stress of the low-temperature material, 22,900 psi. The stabilized materials in common use did not have enough strength. Careful control during operation eliminates corrosion and makes possible the use of unstabilized AISI type 316 stainless steel for the high-temperature service. This steel has the highest creep strength of the heat-resisting stainless steels for which data are available.⁸ Its strength for 1 per cent elongation in 10,000 hr is 23,000 psi.

AISI type 316 alloy is relatively refractory in piercing and rolling and has a tendency to surface-marking. It is therefore common practice to cold-draw this tubing to produce suitable surfaces, to eliminate notches and other stress raisers, and to save material. In addition, some cold work is applied to achieve some recrystallization on heat-treatment and to produce optimum grain size.

FITTINGS

The high-pressure fittings, consisting of tees, ells, and reducers, were forged from special steels required for the various temperature ranges. The tees were formed by forging solid blanks into the proper shape; these forgings were then bored to proper inside dimensions. Because of the thick walls required, it was very difficult to deform the entire mass sufficiently to modify completely the original cast structure. The ells were forged from straight bars, which were first bored eccentrically and then formed with the heavy side on the outside of the bend, in an attempt to secure uniform wall thickness.

Low Temperature. Zones of weakness in the high-pressure tees were found in the branch run. Here a minimum of work was required for the actual shaping of the forging. Fig. 4 shows a carbon-steel tee leaking at a pressure of 8000 psi during a hydrostatic test. Fig. 5 shows the cast (unworked) and the fibrous (partly worked) structures at the fractured surface of a defective tee, which had been broken to show the cause of leakage.

FIG. 4 DEFECTIVE CARBON-STEEL TEE LEAKING UNDER HYDROSTATIC TEST PRESSURE OF 8000 PSI

FIG. 6 DEFECTIVE AISI TYPE 304 STAINLESS-STEEL ELL CAUSED BY FORGING AT TOO LOW A TEMPERATURE

Other tees exhibited forging cracks, laps, and seams at the root of the branches; ells had some checks and laps, but few of these proved to be serious.

Intermediate and High Temperature. The intermediate-temperature forgings were of AISI type 304, and the high-temperature forgings were of AISI type 316 stainless steel. The forging range of these materials is very critical and narrow; 2200 to 1800 F. Forging at temperatures either slightly above or below these limits will result in cracks and checks. More blows are required to work these materials than are required for carbon steel, and the first few blows must be light, so as to harden and toughen the surface, after which heavier blows may be applied. Because of low thermal conductivity, very rapid cooling, and longer forging time, reheating must be done quite often. It is extremely important that the hot-work finish temperature be adhered to, since this material tends to work-harden while still very hot. Fig. 6 shows a forged ell which is believed to have been cracked, owing to forging at too low a temperature.

WELDING OF TUBING

In the fabrication of spool pieces by welding, the metallic-arc process was used exclusively, utilizing multipass procedure. Procedures and operators were qualified on the materials and thick-

FIG. 5 TYPICAL STRUCTURE OF DEFECTIVE CARBON-STEEL TEE WHICH LEAKED UNDER HYDROSTATIC TEST

nesses involved. The joint design employed the conventional $37\frac{1}{2}$ -deg straight bevel for wall thicknesses up to $\frac{3}{4}$ in.; above this thickness a 20-deg U-type bevel was used. Backup rings were not used for the following reasons: (1) The small ID of the tubing made it impossible to remove the rings; (2) restriction to flow caused by a ring would be undesirable; rings would establish starting points for sedimentation and coke formation; (4) damage could result to valves or pumps, were a ring to come loose; (5) it was demonstrated that 100 per cent penetration could be obtained without the use of rings.

Tube tolerances often resulted in $\frac{1}{8}$ in. eccentricity. To prevent shoulders at the joints and to assure full penetration of the weld, the eccentric ID was taper-counterbored at the time of cutting the welding bevel. This also assured alignment of the inside diameters when the outside diameters were aligned, and facilitated setup of the spool pieces before welding.

Low-Temperature Material. Welding of the MT-1040 low-temperature material was difficult because of the high carbon content. To diminish the cooling rate and hardness of the heat-affected zone, a preheat of 400 F was used and maintained during welding. The length of time the preheat was applied was governed by the wall thickness involved. Contrary to common practice of using electrodes with minimum tensile strength at least equal to that of the parent metal, E-7010 electrode was used for the low-temperature-range steel. This choice sacrificed ultimate strength for a gain in ductility; however, yield values of the filler metal exceed yield values of the parent metal. The joint and the heat-affected areas were stress-relieved immediately upon completion of the weld. The heat-affected zone was heated to 1250 F, held at this temperature for 1 hr per in. of wall thickness, and slowly cooled in still air. In no case did the heat-treatment last less than $\frac{1}{2}$ hr. No attempt was made to restore the metal to the normalized condition as it was felt that the stress-relieved weld deposit would meet the necessary tensile requirements.

Intermediate-Temperature Material. Welding of the air-hardening chromium-molybdenum steel also required care. A preheat temperature of 600 to 800 F was used to insure a minimum of 500 F, and thus prevent cracking. Upon completion of the weld, and without any loss of temperature, the joint and heat-affected zone were soaked for 2 hr at 500 F to assist martensite transformation, so that, upon heating to 1200 F (subcritical temperature), holding for 4 hr, and cooling in still air, the weld would be tempered. A filler metal of composition similar to the parent metal was used.

High-Temperature Material. The austenitic AISI type 316 stainless steel required a preheat of 400 F, because of its low ther-

mal conductivity and because of the large mass of metal involved. To assure an austenitic weld deposit and to avoid possible sigma-phase formation, a 25 per cent chromium-20 per cent nickel electrode was used. Because of the high-temperature service condition, postheat was unnecessary.

MACHINING

Machining of the tube ends for the flanged lens joints also presented problems. To effect a seal, the tube ends had to have a smooth machine finish on a 20-deg bevel. This finish was obtained by means of a forming tool. Hard spots in the tube ends, however, would cause chatter of the tool bit and result in marks on the critical bevel face. Kerosene used as a cutting lubricant eliminated much of this trouble.

Tube and flange threads were gaged with "go" and "no-go" gages. If a tube thread were near the large limit and a flange thread near the small limit, binding would occur. This was especially troublesome with AISI type 316 material, which tended to gall. Cutting the tube thread deeper would not remedy a tight fit, but only change the thread profile. However, tube threads could be cut slightly oversize to accommodate oversize flanges. To eliminate this trouble, flanges and thread taps were supplied to the pipe-spool fabricator so that individual fitting could be achieved. These flanges were then used as thread protectors during shipping of the fabricated spool pieces. The critical bevel faces of the pipe spools had to be well protected also, for considerable time could elapse before a particular spool might be used. During this time the spool piece would lie in the pipe yard. Cosmolene was used to prevent corrosion, especially of the carbon steel, and various types of caps and plates were used to prevent damage. Even so, it was necessary to reface many tube ends before some pipe spools could be installed. This refacing was best accomplished by a tool similar to that shown in Fig. 7.⁹ The collar holds the tool square with the axis of the tube, and the

FIG. 7 TUBE-REFACING TOOL

straight cutting edges are mounted so as to sweep an imaginary, 140-deg, included, cone angle. This arrangement produces the required 20-deg bevel on the tube end. The tool is manually operated and care is exercised to maintain uniform rotation of the cutters when they are backed off. This precaution is necessary to prevent marking of the bevel face at the termination of the cut.

The other critical element of the flanged joint—the lens gasket—presented no serious fabrication difficulties. In all tempera-

ture ranges, the materials used for the lens gaskets were softer than the tube ends they were to seal. In the low-temperature range, the gaskets were made of AISI-1020 steel having a maximum Brinell hardness of 140. For the intermediate and high-temperature lens gaskets, AISI type 405 chromium stainless steel was used with a maximum Brinell hardness of 130. Impurities and lack of homogeneity caused voids in the middle of a forged bar of this material which did not show up until 26 pieces, approximately 1 1/2 in. long, had been cut, Fig. 8. The spherical surface of the lens gasket was a polished finish; however, since

FIG. 8 PIPE IN AISI TYPE 405 STAINLESS STEEL

manufacture was done at the job site as needed, corrosive and handling damage was minimized and refacing could be accomplished easily.

OTHER PROBLEMS

The process equipment, including valves, pumps, heat exchangers, instruments, and vessels, is subjected to the same operating conditions as the tubing. Special steels and careful fabrication were required on these elements also. Hence special problems pertaining to each arose.

Materials. Cemented carbide is used for disks and seats of throttling valves and control valves. This material is very hard, but also very brittle, and slight pressure will cause fracture. It is therefore inadvisable to close these valves completely. Where both control and complete stoppage of flow are required, it is necessary to install throttling and stop valves in series. In some cases the cemented-carbide disks were replaced with stellite or hardened stainless steel, having less abrasive resistance but more toughness.

Two materials used for Bourdon tubes are straight 12 to 14 per cent chromium stainless steel and chromium-vanadium steel. Several chromium tubes failed after 5 days under hydrogen pressure. Tubes of similar material have been known to fail after short service in refinery operation because of corrosive attack of a deep cellular nature which causes excessive stress concentrations at tube corners. Fractures of the tubes in question also originated at corners of the cross section, and it is believed that similar attack occurred. Two of the chromium-vanadium tubes failed after 24 hr under hydrogen pressure. Fig. 9 illustrates a typical failure; in this case caused by corrosion fatigue. As a solution to this problem, tube-material specifications have been changed to a corrosion-resistant material, AISI type 316 stainless steel.

Welding. Welded pressure parts of equipment have to withstand the same service as welded tube joints. The proper preheat and postheat must be used regardless of how small the pressure

FIG. 9 BOURDON-TUBE ASSEMBLY AFTER RUPTURE FROM HYDROGEN PRESSURE OF 12,000 PSIG

FIG. 11 COLLAPSED THERMOCOUPLE WELL

FIG. 10 FAILURE OF WELD ON AISI-1025 CARBON STEEL

FIG. 12 WELDED TEE

part might be; the electrode and welding bevel must be suitable for the materials and the thicknesses involved. One of the most important requirements is qualification of the welding operator.

Fig. 10 shows the weld failure of a plug connection of a sample bomb made of AISI-1025 steel which possesses good weldability. When joining light sections to heavy sections, the heavier section must be preheated to obtain good fusion and to avoid quenching the weld. The single-bead-weld fracture displayed a very brittle structure which would indicate insufficient preheat.

Seal welds were one of the most frequent weld failures. Several plugs in heat-exchanger header blocks leaked after a short time under pressure, and numerous pump-block plugs leaked during the pump break-in period. In both cases the weld was too small. Regardless of the tightness of a mechanical seal, the heat of the seal weld will in most cases destroy the fit. A good practice is to employ a seal-weld design capable of withstanding full pressure and to disregard any advantage that may be derived by mechanical means.

Machining. Thermocouple wells of stainless steel were difficult to machine. Two sizes are required: $11\frac{1}{4}$ in. long \times $\frac{9}{16}$ in. OD \times $\frac{3}{16}$ in. ID and $9\frac{3}{8}$ in. long \times $\frac{9}{16}$ in. OD \times $\frac{3}{16}$ in. ID. Both sizes reduce down near the tip to $\frac{9}{16}$ in. OD \times $\frac{1}{8}$ in. ID with a wall thickness of $\frac{2}{32}$ in. which is subjected to a collapsing pressure of 10,300 psig. The wells are turned from solid bars which are then drilled for the thermocouple leads. Drill drift resulted in eccentricity, thin walls, and subsequent failure as shown in Fig. 11. To eliminate the trouble, tips of all the wells were cut. Ec-

centric wells were rejected and concentric wells were reclaimed by welding repair. Replacements were made in two sections and welded together.

CONCLUSIONS

Experience gained in the construction of the hydrogenation demonstration plant evinces many possible improvements.

Some changes in materials and fabrication methods were made during the latter stages of construction. Most of these were effected because of a particular problem and have already been discussed. However, one change that was made to obtain better weldability and to lessen heat-treatment requirements was the use of AISI-4130, chromium-molybdenum steel for low-temperature tubing.

Investigation is being continued to find the most suitable materials to be used in contact with hydrogen at high pressures and temperatures.

One particular development in fabrication procedure is a welded-tee connection. This type of construction could be used to replace forged tees and thus eliminate two joints. An additional advantage is a close control of the material involved, Fig. 12.

Because of the seriousness of failures, one of the most stringent requirements in the construction of high-pressure and high-temperature plants is careful inspection. Materials must be thoroughly checked as to quality and suitability. Design must be commensurate with service conditions. Fabrication must be in accordance with the highest standards of workmanship.

Design of Preheaters and Heat Exchangers for Coal-Hydrogenation Plants

By P. W. LAUGHREY,¹ W. I. GWILLIM,¹ H. SCHAPPERT,² AND J. A. MARKOVITS³

The preheater and the heat-exchanger possibilities of the coal-hydrogenation process are described. Comparison has been made between the demonstration and the German plant equipment. Emphasis has been placed on the importance of developing applicable high-pressure heat exchangers for commercial-size plants, in order to eliminate the preheaters and increase the thermal efficiency of the process.

INTRODUCTION

AN important step toward improving the economic aspect of the coal-hydrogenation process is to achieve high thermal efficiency. Various means have been suggested for a high thermal efficiency. Full utilization of the exothermic heat of reaction through an efficient heat-recovery system and proper preheater design become important in achieving this goal. Possible improvements in design and heat recovery are discussed herein.

PURPOSE OF PASTE PREHEATER

The function of the liquid-phase preheater is to raise the temperature of the coal paste-hydrogen mixture at 10,300 psi pressure from 250 F inlet temperature to about 815 F, before the mixture enters the converters. The reaction in the converters is highly exothermic. The amount of heat developed in the converters compares favorably with that necessary for preheating the paste to the reaction temperature. A summation of all of the reactions occurring in the converter during operations gives a mean heat of reaction of 800 Btu per lb of moisture and ash-free coal converted. This paste has about 40 per cent moisture and ash-free coal content (see Table 1), which means that 1 lb of moisture and ash-free coal makes 2.5 lb of paste. Gas is added to the paste in a ratio of about 16 standard cu ft per lb of paste. Therefore the preheating of this paste and gas requires the following heat quantities per pound of moisture and ash-free coal input:

$$\begin{aligned} 2.5 \times 0.54 \times (815-250) &= 770 \text{ Btu} \\ 40 \times 0.02 \times (815-100) &= 570 \text{ Btu} \\ \text{Total} &= 1340 \text{ Btu} \end{aligned}$$

From this computation it can be seen that the amount of heat needed for preheating the paste proper is approximately the same as the amount of the heat of reaction. It is obvious that with good heat exchange between feed and product, not only is no external heat needed, but a surplus of the major portion of the reac-

tion heat must be removed. Consequently, with a good product-feed heat exchange, there would be no need of a preheater. A small preheater would be needed only for start-up, and the size of this preheater would depend entirely on the length of time to reach full operating conditions. However, it is known that in the German plants, the preheater, especially for subbituminous-coal operation, was a very large and expensive piece of equipment which transmitted a large quantity of heat to the paste. The reason for this fact is to be found, for the most part, in the properties of the coal paste.

PROPERTIES OF THE PASTE

The main property of the coal paste which may determine the design and size of the coal-paste preheater is the viscosity. The change of viscosity of paste with temperature is shown in Fig. 1. An analysis of coal paste is presented in Table 1.

TABLE 1 ANALYSIS OF ROCK SPRINGS COAL PASTE

FIG. 1 VISCOSITY OF COAL-PASTE FEED

The products of hydrogenation, such as gasoline, Diesel oil, and the intermediate heavy-oil products, do not deviate from the ordinary behavior of natural hydrocarbons in regard to viscosity; but the coal paste has a singular behavior concerning viscosity, and this is caused by the swelling properties of the coal. The pulverized coal and the pasting oil are mixed, thereby surrounding each particle of coal with oil. The thickness of the oil film on the coal particles is determined by the ratio of pasting oil to coal and the sum of the entire surfaces of these coal particles. As long as

¹ Chemical Engineer, Coal-to-Oil Demonstration Branch, Office of Synthetic Liquid Fuels, Bureau of Mines, Louisiana, Mo.

² Special Engineer, Koppers Company, Inc., Louisiana, Mo.

³ Assistant Chief, Coal-to-Oil Demonstration Branch, Office of Synthetic Liquid Fuels, Bureau of Mines.

Contributed by the Petroleum Division and presented at the Petroleum Mechanical Engineering Conference, Oklahoma City, Okla., October 2-5, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-PET-1.

the oil film has a certain thickness, the viscosity of the paste is determined mainly by the viscosity of the pasting oil; but within a certain range, the coal swells, and consequently the viscosity increases markedly. This happens even in the presence of hydrogen, because at the beginning of the heating cycle the temperature is too low for hydrogenation of the coal. At higher temperatures hydrogenation and liquefaction take place, and the viscosity begins to decrease. The factors affecting this peculiar behavior of the paste are: Origin of the coal, solids content of the paste, fineness of the coal particles, and asphalt content of the pasting oil. In general, younger coals do not exhibit as marked a viscosity change in the swelling range. Increase of all the other factors mentioned tends to promote an increased viscosity of the paste in the swelling range.

Obviously, at a high viscosity of the paste, the heat transfer in the preheater is poor, and at a low viscosity it is good. Translating this viscosity effect into a more usable term, that of paste-film coefficient, the curve shown in Fig. 2 results. In the swelling-temperature range the paste-film coefficient reaches a minimum, and it improves with the beginning of the liquefaction. Since the tube-wall temperatures of the preheater are calculated by means of the paste-film coefficient, a knowledge of the values of this coefficient is very important. Characteristics of pastes derived from the various types of U. S. coals will be investigated in the preheater of the demonstration plant.

DESCRIPTION OF PASTE PREHEATER

An isometric drawing of the paste preheater is shown in Fig. 3. Because of the unusual viscosity and heat-transfer characteristics of the paste, which have been described, the paste preheater was designed with four separate cells, which are fired independently for optimum temperature control. It will be noted from the drawing that eight vertical hairpins are contained in each cell. The $2\frac{1}{2}$ -in-ID hairpins are surrounded with a 5-in-ID steam jacket, and the steam-jacket tube is exposed to radiant heat. The high-pressure tube is made of type-316 stainless steel, and the steam tube is made of 4 to 6 per cent chrome, and $\frac{1}{2}$ per cent molybdenum steel with dimensions as shown. The steam jacket

PASTE WITH 46% SOLIDS
BASED ON GERMAN DATA

FIG. 2 PREDICTED FILM COEFFICIENTS OF COAL PASTE

promotes equal distribution of heat throughout the circumference of the high-pressure tube and aids in controlling the tube-metal temperatures.

Design data for the paste preheater applicable to operation on Rock Springs coal are given in Table 2.

OPERATION OF PASTE PREHEATER

The paste, with a small amount of gas, enters the first cell of the preheater. Addition of the gas improves the flow conditions, and therefore, the heat transmission. Between the first and second cells of the preheater, at about 570 F paste temperature, two outside streams are introduced into the paste. One is a hot stream of hydrogen at 710 F. The other stream is a heavy solids-containing oil, called "heavy-oil letdown" (HOLD). This latter stream flows hot (775 F) directly from the bottom of the hot

catchpot and is boosted with a surge-type pump. The injection of these two hot streams produces a sharp temperature rise in the paste to about 630 F, thereby causing the paste to pass over the swelling range of the coal quickly. Also, enough hydrogen is introduced into the paste to start the liquefaction of the coal.

The velocity in the coal-paste preheater is an important design factor. For the foregoing design conditions the velocities are cell No. 1, 3 fps; cell No. 2, 8.5 fps; cell No. 3, 9 fps; cell No. 4, 9.5 fps.

The velocity in the last three cells is increased owing to the addition of the hot gas and heavy-oil let-down. In the German plants, experience showed that a velocity of 15-20 fps was quite suitable for 4-in-ID preheater tubes. This velocity range assured a uniform flow of paste throughout the preheater, was under the erosion limit of approximately 25 fps, and did not cause an excessive pressure drop across the preheater.

Operating conditions for Rock Springs coal have been established, and various temperatures in the preheater under these conditions have been calculated as shown in Fig. 4. Fig. 5 shows that even if some coking of the tubes should occur, only a slight decrease in throughput is required to maintain tube-metal temperatures below the maximum allowable, 1000 F.

The throughput of various coals in the demonstration plant will vary according to the ease of hydrogenation, and therefore

the design velocities in the paste preheater are purposely rather low, in order to accommodate coals that hydrogenate easily. The demonstration-plant preheater is, therefore, suitably designed to solve all the problems involved in experimentation with all varieties of American coals.

LARGE-SCALE PASTE-PREHEATER INSTALLATIONS

All German preheaters were of the convection type. Tubes were arranged vertically in the form of hairpins in narrow cells in which flue gas was circulated at fairly high velocity. These hairpins were finned tubes with an outside:inside surface ratio of 20:1, to compensate for the low film heat-transfer coefficient on the flue-gas side. Tube-metal temperatures were controlled by regulating the quantity and temperature of the circulated flue gas.

A plan view of such a preheater is shown in Fig. 6. The inlet connections for heavy-oil and hot paste gas, shown in this drawing, indicate that the swelling range of the coal in this preheater was bridged in a similar manner to that in the preheater of the demonstration plant.

All things being equal, such as duty and maximum allowable tube-metal temperature, the total heating-surface requirement, based on inside area of the high-pressure tube is approximately the same for the finned-tube convection-type, the radiant-type, or the steam-jacketed radiant-type preheater of the demonstration plant. The reason for this fact is that the paste film represents 80 to 90 per cent of the total resistance to heat flow; therefore it is the determining factor in calculating the total surface requirement. The resistance to heat flow on the outside of the high-pressure tubes is lowered by the compensatory highly finned surface in the convection type, and the high-velocity steam flow in the steam-jacketed radiant type. A proper selection of a preheater for large-scale installations, therefore, must discard the convection type because of the added capital cost of fabricating the finned surfaces and the auxiliary equipment such as ducts and blowers. In comparing the conventional radiant type with the steam-jacketed radiant-type preheater, the operational features of the latter such as uniformity of heat distribution, prevention of coking, and optimum process control, must outweigh its slightly greater cost. It is conceivable that in the plant of the future a

FIG. 6 PLAN VIEW OF CONVECTION-TYPE PREHEATER

conventional radiant-type preheater with low heat densities would be feasible. It can be designed along the following lines: The multicelled setting would take the form of a long, rectilinear box with hairpin tubes suspended from the roof in the center of the box. Firing would take place on each side of the box with short-flame burners and good burning characteristics, permitting wide variations in firing rate, with minimum percentages of excess air.

VAPOR-PHASE PREHEATER

For the first time in coal hydrogenation at 10,000 psig, a radiant-

type preheater is used in the vapor-phase hydrogenation demonstration plant. This preheater is gas-fired, contains thirty $1\frac{1}{4}$ -in-ID type 316, stainless-steel horizontal tubes arranged in two parallel streams, and has a design duty of 1,890,000 Btu per hr. Feed to the preheater consists of middle oil from the liquid-phase operation (620 F end point), and recycle oil from the vapor-phase distillation, which, together with hydrogen, comes from the product-feed exchanger with a temperature of about 780 F to the preheater. The preheater superheats the oil vapors to reaction temperature or to about 900 F.

Design data for the vapor-phase preheater are given in Table 3.

Both the liquid- and vapor-phase preheaters were furnished by Alcorn Combustion Company, Philadelphia, Pa.

HEAT EXCHANGERS

The foregoing discussion shows how important it is to provide good heat exchange and how necessary it is to utilize fully the heat of reaction in the converters. The demonstration plant, however, was purposely not designed for maximum heat recovery, since the additional expense could not be justified in such a small plant. There are 40 heat exchangers in the plant. Thirty-one exchangers are designed for low-pressure service in the distillation and storage areas. Nine exchangers are designed for 700-atm operation in the liquid- and vapor-phase hydrogenation. All except the HOLD cooler are double-pipe exchangers, and only two of these high-pressure exchangers service process streams with the full 10,300 psi in both tubes. The wall thickness of the inside tube in these two exchangers is only 8 gage. It is designed for a differential pressure of 2000 psi so that testing and starting has to be done with both tubes under pressure. The other high-pressure exchangers are designed with full 10,300 psi operating pressure on the inside tube, the outside tube consisting of a low-pressure tube jacket in which either cooling water or low-pressure oil is flowing. The tube jackets are constructed of carbon steel, and the high-pressure tubes of 8-10 per cent chrome and $\frac{1}{2}$ per cent molybdenum alloy. The HOLD cooler is a forced-draft air cooler with eight hairpins, made with Croloy-9M tubes, 30 ft long and 1 in. ID, connected in series flow. The cooling air passes downward at 58 fps through a 64-in. \times 10-in. rectangular duct enclosing the

hairpins. All exchangers in high-pressure service were supplied by Industrial Engineers, Inc., Los Angeles, Calif.

The demonstration plant was designed in order that the following information may be obtained: (1) Heat balances to determine where the different heat quantities occur and in what relationship they occur; (2) the type of heat-exchange equipment most suitable for a particular heat-exchange job; and (3) determination of film heat-transfer coefficients and fouling factors. This information will be obtained on only the high-pressure equipment, since heat-exchange design in the low-pressure area follows conventional petroleum-refinery practice. All of the points mentioned must be investigated with the view of obtaining design data for commercial plants. As an example of the type of information to be obtained, a heat balance around the liquid-phase stall of the demonstration plant has been calculated as shown in Table 4 and summarized in Fig. 7.

Although this heat balance is applicable to the demonstration plant, the heat ratio of the top and bottom products will be maintained in commercial plants. This ratio is approximately 12,000,000 : 3,000,000 Btu per hr or 4 to 1. Heat exchange can best be carried out on the top product. The heat balance shows that the heat contained in the top product is sufficient to supply the following requirement:

Heat required:	
3793 lb per hr hydrogen.....	2,750,000
20,183 lb per hr paste (preheater).....	6,740,000
Total.....	9,490,000

Heat available from top product of the hot catchpot, Btu per hr.....	12,280,000
---	------------

It can be seen that the heat required is only about 75 per cent of the heat available. The problem is how to utilize fully this heat, and one answer to the problem may again be found in later German developments. These developments introduced a heat-exchange procedure in which two paste streams of different solids content were used. Thick paste with a total solids content of 53 per cent was heated in an exchanger train up to its swelling tem-

perature of 570 F. A thin paste with 42 per cent solids content made by diluting the thick paste with pasting oil, was heated in another exchanger train up to full reaction temperature with no difficulty. These two streams were then combined, and the remaining heat supplied in a small preheater. This procedure was not as advantageous as it should have been because of wide fluctuations in solids content of the various paste batches due to poor mixing technique.

It is anticipated in a projected 30,000-bbl per day coal-hydrogenation plant that a nearly perfect heat exchange can be achieved using a single paste with 47 per cent total-solids content. To do this, however, improved mixing controls must be introduced in order to insure a constant quality of paste. The preparation of the coal must also be such that all fines are eliminated from the process coal. These may be burned in the power plant. The heat-exchange system for the 30,000-bbl per day plant is shown in Fig. 8. The paste flow is divided into two streams, in such a manner that the larger stream (approximately 75 per cent), is heated up in exchangers to the reaction temperature without a preheater. The smaller stream is heated in exchangers to as high

a temperature as the remaining heat will allow, and further heat requirement is supplied with a small preheater. The extent of improvement by carrying out the foregoing procedure can be shown by comparison with conventional German design, that is, 3 times the German throughput can be obtained with the same number of preheaters of smaller duty.

Since the total heat requirement of the process can be supplied from the top products of the hot catchpot, the question arises as to how the heat from the bottom products can be used economically. There are several considerations as follows:

1 In the demonstration plant, the feasibility of a flash distillation of the heavy-oil let-down (HOLD) will be determined. Therefore it may be possible that in larger plants the bottom product of the hot catchpot may be flash-distilled without cooling.

2 If it becomes necessary to cool the HOLD for other treatment, such as centrifuging, steam can be produced by jacketing the HOLD lines.

3 If there is no need or demand for steam, the temperature can be lowered by a combination of air-and-water cooling.

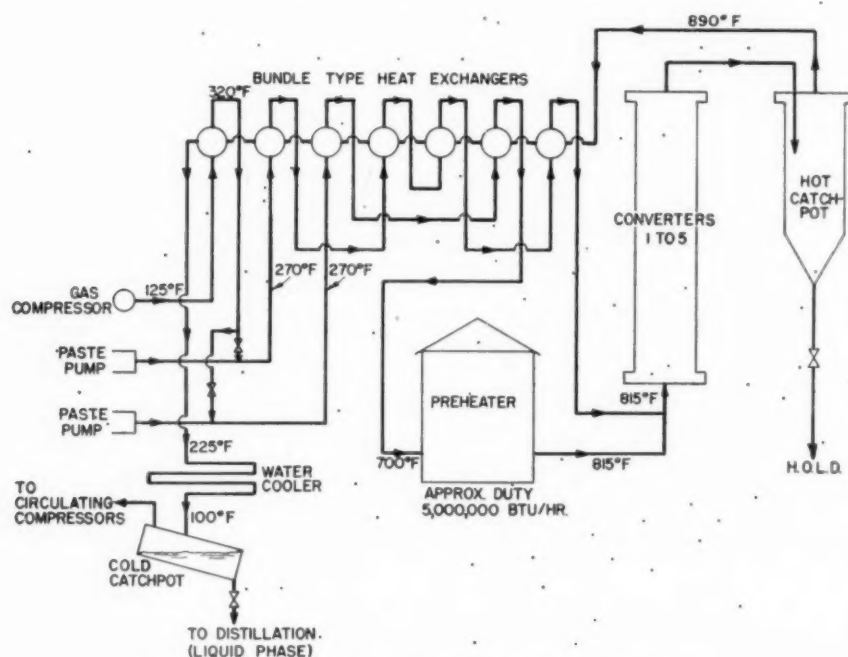

FIG. 8 PROPOSED HEAT-EXCHANGE SYSTEM FOR COMMERCIAL PLANT

There is no hot catchpot in the vapor-phase hydrogenation plant, and the heat of reaction is very high. Therefore a better heat exchange can be established in the vapor phase than in the liquid phase. The vapor-phase section can be operated without any external heat supply. Only a small preheater is necessary for starting-up operations.

The heat exchangers which were used in Germany were the shell-and-tube type designed for 10,000 psig operating pressure and placed in a vertical position. The bundle was inserted in a high-pressure internally insulated vessel and connected outside by means of a stuffing box on the top of the heat exchanger. The paste-feed stream flowed outside the tubes from bottom to top, and the product inside the tubes from top to bottom. The center-to-center distance of the tubes was determined by fabricating limitations and by the composition of the paste feed, that is to say, by the clogging tendency of the paste to form bridges between the tubes. A single design and size were used in both liquid-phase and vapor-phase operation. The tubes of this exchanger were designed for the full operating pressure of 10,000 psig. The bundle was designed with 199 tubes, (0.55 in. ID \times 0.91 in. OD), about 57 ft long, for use in a high-pressure vessel of 22 in. ID. The average heating surface was 2150 sq ft. Originally, forged shells were used, but later designs were based upon wrapped or spiral-wound construction.

In designing high-pressure heat exchangers for commercial plants, consideration has to be given to: (1) The thickness and material of the tube walls; (2) the minimum distance between center to center of the tubes; (3) pressure difference of the gas-recycle compressors, in order to determine the cross section of the heat-exchanger bundle; and (4) equal distribution of the product and the feed through the heat exchanger.

In special cases, for instance, with the heavy-oil letdown, double-pipe exchangers are quite effective. The HOLD stream flows through the tubes and the medium to be heated through the annular space. These double-pipe exchangers for 700-atm design pressure are cumbersome, owing to the extreme wall thickness.

FILM HEAT-TRANSFER COEFFICIENTS

Film heat-transfer coefficients of all gases increase greatly with pressure at constant linear velocity, as shown in the calculated example for pure hydrogen in Table 5. This, combined with the fact that the thermal conductivity of hydrogen is about 10 times that of other gases such as nitrogen, carbon monoxide, and carbon dioxide, makes for high film coefficients in coal-hydrogenation heat-exchange equipment.

The principal consideration in determination of the film co-

TABLE 5 EFFECT OF PRESSURE ON FILM HEAT-TRANSFER COEFFICIENT OF PURE HYDROGEN

Calculated film heat-transfer coefficient, Btu per hr-ft ² -deg F.....	9	115	2100

efficient of the gas streams is the hydrogen purity, due to the effect of the high thermal conductivity of hydrogen on the film-transfer coefficient. Since the film coefficient for hydrogen-containing gases is high, especially at 700 atm, the use of the correct fouling factor also becomes very important. Fouling is quite rapid on new exchangers; therefore a film coefficient of about 110 Btu/hr-ft²-deg F for hydrogen of 80-90 per cent purity flowing at a velocity of about 15 fps, is a reasonable design figure.

Since coal paste is always heated up in the presence of hydrogen, its high thermal conductivity increases the film coefficient of the paste. The film coefficient is highly dependent on the solid concentration of the paste, and also on the fineness of the pulverized coal; but the fact was established in Germany that the film coefficient for the same paste was higher in the heat exchangers than in the preheater within the same temperature range. This effect was contributed to a better flow distribution through the heat-exchanger bundle. The film-coefficient values varied from 80-120 Btu/hr-ft²-deg F in the paste heat exchangers with a paste velocity of 8 fps.

Film coefficients range from 130-160 Btu/hr-ft²-deg F for middle oil and hydrogen in the relative portions used in vapor-phase hydrogenation where 15 to 30 cu ft of hydrogen is used per lb of oil at velocities from 6 to 15 fps. This range applies after a few months of operation.

The film coefficients for heavy-oil letdown (HOLD) have been determined from German data on air coolers. This coefficient varies with solids and asphalt content of the HOLD, but an average figure for this coefficient is 90 Btu/hr-ft²-deg F at velocities ranging from 9 to 15 fps and at temperatures above 400 F.

The German data quoted in this report were useful in designing the demonstration plant, and it is hoped that the operation of the plant will furnish the necessary information on all varieties of American coals. When these data are determined, perhaps an ideal heat-exchange system for future big-scale plants can be designed in both phases, and the use of both preheaters will become obsolete.

A Simple Hydrodynamic Thrust Bearing

By F. R. ARCHIBALD,¹ PRINCETON, N. J.

Considerable mathematical difficulty has handicapped the designer in the application of the hydrodynamic theory of lubrication. This difficulty arises essentially from the shapes assumed by the oil films. In 1918 Lord Rayleigh gave a detailed analysis of the simple slider bearing, neglecting the side-leakage effect, in which he determined that the greatest load capacity occurs when the slider element gives a stepped convergence to the oil film. From the simple geometry of this oil film, a solution, taking account of side leakage, might be obtained fairly easily. The author proves this to be so, and gives solutions for the case of rectilinear motion with finite bearing width, and also the more practical sectorial case of a thrust bearing.

APPLICATIONS of the theory of lubrication have been handicapped by the considerable mathematical difficulties encountered in the solution of practical problems. Even in the elementary case of a flat inclined plate of finite width, the solution, given by A. G. M. Michell, is so difficult as to discourage much hope for the solution of many other practical problems.

Much of the mathematical difficulty arises from the shapes taken by oil films. Therefore, if a bearing can be devised in which the oil film has a simple shape there is a good prospect that an analytical solution can be given for its performance.

It might be thought impossible to obtain an oil-film shape simpler than that given by the inclined flat plate, but there is such a shape. At least there is a configuration much simpler to deal with in the lubrication problem.

In 1918 Lord Rayleigh² gave a detailed analysis of the simple slider bearing neglecting the side-leakage effect. He considered various shapes for the surface of the slider element. After showing very slight improvement in the load capacity when the slider surface was curved instead of being flat, he then set the variational problem to find the best possible shape from the point of view of load capacity. The result of this analysis was to show that greatest load capacity occurs if the slider element is made as shown in Fig. 1, giving a stepped convergence to the oil film.

The results of the flat inclined slider-bearing calculation, when side leakage is neglected, are well known. For a given viscosity, speed, length of slider, and minimum film thickness, μ , U , c , and h_1 , respectively, the maximum load per unit width is given by

$$W_{\max} = \frac{0.160\mu U c^2}{h_1^2}$$

With the shape given by Rayleigh it is possible to have a maximum load per unit width of

$$W_{\max} = \frac{0.206\mu U c^2}{h_1^2}$$

² "Notes on the Theory of Lubrication," by Lord Rayleigh, *Philosophical Magazine*, vol. 35, 1918, pp. 1-12.

Contributed by the Research Committee on Lubrication and the Petroleum Division and presented at the Annual Meeting, New York, N. Y., November 27-December 2, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-A-29.

FIG. 1

This is about 29 per cent greater than for the inclined flat-plate bearing.

It would appear that with the simple geometry of this oil film, a solution, taking account of side leakage, might be fairly easy to obtain. This turns out to be so and solutions are given both for the case of rectilinear motion with finite bearing width and also the more practical sectorial case of a thrust bearing.

CASE WITH NO SIDE LEAKAGE

Before proceeding to the more complicated three-dimensional problem the case with no side leakage might be considered to advantage. The "calculus of variations" is perhaps not familiar to many who may be interested in the problem, and in any event this method of solution is available in Rayleigh's more elegant paper. Therefore the results will be obtained by the usual methods, but starting with the stepped-film shape. The notation will be the same as in Rayleigh's paper.²

From a consideration of the shear stress and velocity gradient in the film it is easily shown that

$$\frac{\partial^2 u}{\partial y^2} = \frac{1}{\mu} \frac{dp}{dx} \quad [1]$$

Upon integrating this equation twice with respect to y and substituting the boundary conditions; $u = -U$ when $y = 0$, and $u = 0$ when $y = h$, the following expression for u is obtained

$$u = \frac{y^2 - hy}{2\mu} - \left(1 - \frac{y}{h}\right) U \quad [2]$$

By integrating this expression over the film thickness the flow per unit width is obtained as

$$-Q = -\frac{1}{12} \frac{h^3}{\mu} \frac{dp}{dx} - \frac{1}{2} U h \quad [3]$$

This same expression for flow in the X -direction is obtained in the side-leakage problem, but in this case it is the rate of flow at a point rather than over a unit width. A partial derivative of p with respect to x is also necessary in this case. Because this relation is needed in the three-dimensional problem it will be given here

$$-q_x = -\frac{1}{12} \frac{h^3}{\mu} \frac{\partial p}{\partial x} - \frac{1}{2} U h \quad [3a]$$

From Equation [3]

$$\frac{dp}{dx} = \frac{6\mu U}{h^3} \left(\frac{2Q}{U} - h \right)$$

Call

$$\frac{2Q}{U} = H$$

Then

$$\frac{dp}{dx} = \frac{6\mu U}{h^3} (H - h) \quad [4]$$

If h is constant this equation can be integrated to give the pressure as follows

$$p = \frac{6\mu U}{h^3} (H - h)x + A \quad [5]$$

The evaluation of A depends on the boundary conditions. It is convenient here (and more so in the three-dimensional problem) to consider the problem for each stepped region separately. The co -ordinate axis being left as in Fig. 1 for region (1) and being moved forward by $(c_1 + c_2)$, i.e., to the leading edge, for region (2).

For region (1) when $x = 0$, $p = 0$ and $A = 0$

$$\therefore p = \frac{6\mu U}{h_1^3} (H - h_1)x \quad [6]$$

For region (2), when $x = 0$, $p = 0$, and $A = 0$

$$\therefore p = \frac{6\mu U}{h_2^3} (H - h_2)x \quad [7]$$

The pressure given by Equation [6] when $x = c_1$ is the same as that given by Equation [7], when $x = -c_2$

$$\frac{6\mu U}{h_1^3} (H - h_1)c_1 = -\frac{6\mu U}{h_2^3} (H - h_2)c_2$$

which upon solving for H gives

$$H = \frac{h_1 h_2 (c_1 h_2^3 + c_2 h_1^3)}{c_1 h_2^3 + c_2 h_1^3} \quad [8]$$

The load for each region is obtained by integrating the pressure over the areas as follows:

For region (1)

$$W_1 = \int_0^{c_1} p dx = \frac{6\mu U}{h_1^3} (H - h_1) \int_0^{c_1} x dx = \frac{3\mu U}{h_1^3} (H - h_1) c_1^2 \quad [9]$$

For region (2)

$$W_2 = \int_{-c_2}^0 p dx = \frac{6\mu U}{h_2^3} (H - h_2) \int_{-c_2}^0 x dx = \frac{3\mu U}{h_2^3} (h_2 - H) c_2^2 \quad [10]$$

The total load, $W = W_1 + W_2$

$$\begin{aligned} \therefore W &= 3\mu U \left[\left(\frac{H - h_1}{h_1^3} \right) c_1^2 + \left(\frac{h_2 - H}{h_2^3} \right) c_2^2 \right] \\ &= 3\mu U \left[H \left(\frac{c_1^2}{h_1^3} - \frac{c_2^2}{h_2^3} \right) + \frac{c_2^2}{h_2^3} - \frac{c_1^2}{h_1^3} \right] \quad [11] \end{aligned}$$

If H from Equation [8] is now placed in Equation [11] the load is obtained as a function of the parameters

$$W = 3\mu U \left[\frac{h_1 h_2 (c_1 h_2^3 + c_2 h_1^3)}{c_1 h_2^3 + c_2 h_1^3} \left(\frac{c_1^2 h_2^3 - c_2^2 h_1^3}{h_1^3 h_2^3} \right) + \frac{c_2^2 h_1^3 - c_1^2 h_2^3}{h_1^3 h_2^3} \right]$$

This expression for W will simplify to

$$W = 3\mu U c_1 c_2 (c_1 + c_2) \frac{h_2 - h_1}{c_1 h_2^3 + c_2 h_1^3} \quad [12]$$

If the total length of the bearing $c = (c_1 + c_2)$, and the minimum film thickness h_1 , are prescribed, the proportions for maximum load capacity can be found as follows

$$c_2 = c - c_1, \quad \text{and let } h_2 = kh_1$$

Then

$$W = \frac{3\mu U c c_1 (c - c_1) (k - 1)}{h_1^3 [c_1 (k^3 - 1) + c]}$$

$W = f(c_1, k)$ and will have a maximum when $\partial W / \partial c_1 = 0$ and $\partial W / \partial k = 0$

$$\frac{\partial W}{\partial c_1} = \frac{3\mu U c (k - 1)}{h_1^3} \times \left\{ \frac{[c_1 (k^3 - 1) + c] (c - 2c_1) - c_1 (c - c_1) (k^3 - 1)}{[c_1 (k^3 - 1) + c]^2} \right\} \quad [13]$$

For $\partial W / \partial c_1 = 0$ it is sufficient that

$$[c_1 (k^3 - 1) + c] (c - 2c_1) - c_1 (c - c_1) (k^3 - 1) = 0$$

which will reduce to

$$k^3 = \left(\frac{c - c_1}{c_1} \right)^2 \quad [14]$$

$$\frac{\partial W}{\partial k} = \frac{3\mu U c_1 c (c - c_1)}{h_1^3} \left\{ \frac{c_1 (k^3 - 1) + c - 3(k - 1) c_1 k^2}{[c_1 (k^3 - 1) + c]^2} \right\}$$

For $\partial W / \partial k = 0$ it is sufficient that

$$c_1 (k^3 - 1) + c - 3(k - 1) c_1 k^2 = 0$$

which will reduce to

$$c_1 = \frac{c}{1 - 3k^2 + 2k^3} \quad [15]$$

From Equation [14]

$$c = c_1 (k^{3/2} + 1)$$

Substituting in Equation [15]

$$c_1 = \frac{c_1 (k^{3/2} + 1)}{1 - 3k^2 + 2k^3}$$

which will reduce to

$$4k^3 - 12k^2 + 9k - 1 = 0$$

The three roots of this equation are

$$k = 1 \text{ and } k = 1 \pm \sqrt{3}/2$$

Obviously, the required value for maximum load is $k = 1 + \sqrt{3}/2 = 1.866$

Now $(c_1 + c_2) = c$, and from Equation [14]

$$c_1 (1 - 3k^2 + 2k^3) = c$$

With $k = 1.866$ these relations make $c_2 = 2.549c_1$

The maximum load from Equation [12] is now found as

$$W = 0.2062 \frac{\mu U c^2}{h_1^2} \quad [16]$$

These results are the same as given by Rayleigh.

STEPPED SHAPED SLIDER

The problem of the stepped shaped slider of finite width will next be considered. In this case a flow perpendicular to the direction of motion, i.e., a side-leakage effect, has to be included and recourse is had to Reynolds partial differential equation for pressure in a lubricating film

$$\frac{\partial}{\partial x} \left(h^3 \frac{\partial p}{\partial x} \right) + \frac{\partial}{\partial z} \left(h^3 \frac{\partial p}{\partial z} \right) = 6\mu U \frac{dh}{dx} \quad [17]$$

The scheme of the bearing is as shown in Fig. 2.

FIG. 2

The region in which h is constant at h_1 is called region (1), and the region in which h is constant at h_2 is called region (2). The X - Z plane is taken as the flat moving element having a velocity $-U$ as shown. It will again be found convenient to use two coordinate systems. For region (1) the co-ordinates are as shown, but for region (2) they will be moved forward so that the Z axis is on the leading edge of region (2).

If h is constant, the right-hand side of Reynolds equation is zero, and h^3 can be divided from the left-hand side leaving

$$\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial z^2} = 0 \quad [18]$$

This is the Laplace partial differential equation.

An interesting incidental result can be obtained at this stage. Consider a rectangular flat plate being moved parallel to another flat plate and separated from it by a fluid film of thickness h , Fig. 3.

In this case Equation [18] applies. However, if Laplace's

FIG. 3

equation applies to a region, on the boundaries of which the function is everywhere zero, the only solution is zero, i.e., $p = 0$ is the solution to the pressure equation in this case. This is a well-known result and is not of course restricted to a rectangular shape.

To return to the problem of the stepped slider. The pressure on the exterior boundaries of regions (1) and (2) is zero, but on the common boundary the pressure is not known. It is assumed that the pressure on this common boundary is given by the following Fourier sine series

$$p = \sum_{n=1,3,5,\dots}^{\infty} P_n \sin \frac{n\pi z}{b} \quad [19]$$

The summation is over the odd values because of the symmetry. P_n is the Fourier coefficient to be evaluated later.

The general solution for p can be put in the following form

$$p = \sum_{n=1,3,5,\dots}^{\infty} \left(A_n \cos \frac{n\pi x}{b} + B_n \sin \frac{n\pi x}{b} \right) \left(C_n \cosh \frac{n\pi x}{b} + D_n \sinh \frac{n\pi x}{b} \right) \quad [20]$$

The boundary conditions for region (1) are

$p = 0$ at $x = 0$ for all values of z I

$p = 0$ at $z = 0$ for all values of x II

$p = 0$ at $z = b$ for all values of x III

$$p = \sum_{n=1,3,5,\dots}^{\infty} P_n \sin \frac{n\pi z}{b} \text{ at } x = c_1 \text{ IV}$$

From conditions I and II, $A_n = C_n = 0$

From condition IV

$$\sum_{n=1,3,5,\dots}^{\infty} P_n \sin \frac{n\pi z}{b} = \sum_{n=1,3,5,\dots}^{\infty} B_n D_n \sin \frac{n\pi z}{b} \sinh \frac{n\pi c_1}{b}$$

$$\therefore B_n D_n = \frac{P_n}{\sinh \frac{n\pi c_1}{b}}$$

$$\therefore p = \sum_{n=1,3,5,\dots}^{\infty} \frac{P_n}{\sinh \frac{n\pi c_1}{b}} \sin \frac{n\pi z}{b} \sinh \frac{n\pi x}{b} \quad [21]$$

For region (2) a solution of the same form as Equation [20] is taken

$$p = \sum_{n=1,3,5,\dots}^{\infty} \left(E_n \cos \frac{n\pi x}{b} + F_n \sin \frac{n\pi x}{b} \right) \left(G_n \cosh \frac{n\pi x}{b} + H_n \sinh \frac{n\pi x}{b} \right) \quad [22]$$

The boundary conditions are

$p = 0$ at $x = 0$ for all values of z I

$p = 0$ at $z = 0$ for all values of x II

$p = 0$ at $z = b$ for all values of x III

$$p = \sum_{n=1,3,5,\dots}^{\infty} P_n \sin \frac{n\pi z}{b} \text{ at } x = -c_2 \text{ IV}$$

From conditions I and II, $E_n = G_n = 0$

From condition IV

$$\sum_{n=1,3,5,\dots}^{\infty} P_n \sin \frac{n\pi z}{b} = - \sum_{n=1,3,5,\dots}^{\infty} F_n H_n \sin \frac{n\pi z}{b} \sinh \frac{n\pi c_2}{b}$$

$$\therefore F_n H_n = - \frac{P_n}{\sinh \frac{n\pi c_2}{b}}$$

$$\therefore p = - \sum_{n=1,3,5,\dots}^{\infty} \frac{P_n}{\sinh \frac{n\pi c_2}{b}} \sin \frac{n\pi z}{b} \sinh \frac{n\pi x}{b} \dots [23]$$

In order that the pressure be calculable the Fourier coefficient, P_n , must now be evaluated. This is done by making use of the principle of continuity. At any point on the common boundary it will be seen that the rate of flow out of region (2) is the same as the rate of flow into region (1). The rate of flow in the X -direction is given by Equation [3a]

$$-q_x = - \frac{Uh}{2} - \frac{h^3}{12\mu} \frac{\partial p}{\partial x} \dots [3a]$$

The equality of the rate of flow for both regions at the common boundary is expressed as follows

$$\frac{Uh_1}{2} + \frac{h_1^3}{12\mu} \left(\frac{\partial p}{\partial x} \right)_{c_1} = \frac{Uh_2}{2} + \frac{h_2^3}{12\mu} \left(\frac{\partial p}{\partial x} \right)_{-c_2} \dots [24]$$

The partial derivative, $\partial p / \partial x$, for regions (1) and (2) must now be evaluated at $x = c_1$ for region (1), and at $x = -c_2$ for region (2).

For region (1)

$$\frac{\partial p}{\partial x} = \sum_{n=1,3,5,\dots}^{\infty} \frac{n\pi}{b} \frac{P_n}{\sinh \frac{n\pi c_1}{b}} \sin \frac{n\pi z}{b} \cosh \frac{n\pi x}{b}$$

$$\therefore \left(\frac{\partial p}{\partial x} \right)_{c_1} = \sum_{n=1,3,5,\dots}^{\infty} \frac{n\pi}{b} P_n \coth \frac{n\pi c_1}{b} \sin \frac{n\pi z}{b} \dots [25]$$

For region (2)

$$\frac{\partial p}{\partial x} = - \sum_{n=1,3,5,\dots}^{\infty} \frac{n\pi}{b} \frac{P_n}{\sinh \frac{n\pi c_2}{b}} \sin \frac{n\pi z}{b} \cosh \frac{n\pi x}{b}$$

$$\therefore \left(\frac{\partial p}{\partial x} \right)_{-c_2} = - \sum_{n=1,3,5,\dots}^{\infty} \frac{n\pi}{b} P_n \coth \frac{n\pi c_2}{b} \sin \frac{n\pi z}{b} \dots [26]$$

Equation [24] is rewritten using the values of $\partial p / \partial x$ from Equations [25] and [26]

$$\frac{Uh_1}{2} + \frac{h_1^3}{12\mu} \sum_{n=1,3,5,\dots}^{\infty} \frac{n\pi}{b} P_n \coth \frac{n\pi c_1}{b} \sin \frac{n\pi z}{b} = \frac{Uh_2}{2} - \frac{h_2^3}{12\mu} \sum_{n=1,3,5,\dots}^{\infty} \frac{n\pi}{b} P_n \coth \frac{n\pi c_2}{b} \sin \frac{n\pi z}{b} \dots [27]$$

which can be rearranged as follows

$$\sum_{n=1,3,5,\dots}^{\infty} \frac{n\pi}{b} P_n \left(h_1^3 \coth \frac{n\pi c_1}{b} + h_2^3 \coth \frac{n\pi c_2}{b} \right) \sin \frac{n\pi z}{b} = 6\mu U(h_2 - h_1) \dots [28]$$

The right-hand side of Equation [28] is expanded in a Fourier sine series by use of the standard sine series for $\pi/4$

$$\sum_{n=1,3,5,\dots}^{\infty} \frac{n\pi}{b} P_n \left(h_1^3 \coth \frac{n\pi c_1}{b} + h_2^3 \coth \frac{n\pi c_2}{b} \right) \sin \frac{n\pi z}{b} = \sum_{n=1,3,5,\dots}^{\infty} 6\mu U(h_2 - h_1) \frac{4}{n\pi} \sin \frac{n\pi z}{b}$$

The Fourier coefficient, P_n is thus

$$P_n = \frac{24\mu U b (h_2 - h_1)}{n^2 \pi^2 \left(h_1^3 \coth \frac{n\pi c_1}{b} + h_2^3 \coth \frac{n\pi c_2}{b} \right)} \dots [29]$$

The pressure can now be calculated at any point by placing this value of P_n in the pressure Equations [21] and [23]. However, the total load on the bearing is of more interest, and this is easily found. The load supported by region (1) is called W_1 and the load supported by region (2) is called W_2

$$W_1 = \int_0^b \int_0^{c_1} p \, dx \, dz$$

$$\therefore W_1 = \int_0^b \int_0^{c_1} \sum_{n=1,3,5,\dots}^{\infty} \frac{P_n}{\sinh \frac{n\pi c_2}{b}} \sin \frac{n\pi z}{b} \sinh \frac{n\pi x}{b} \, dx \, dz$$

$$= \int_0^b \sum_{n=1,3,5,\dots}^{\infty} \frac{b}{n\pi} \frac{P_n}{\sinh \frac{n\pi c_2}{b}} \left(\cosh \frac{n\pi c_1}{b} - 1 \right) \sin \frac{n\pi z}{b} \, dz$$

$$\therefore W_1 = \sum_{n=1,3,5,\dots}^{\infty} \frac{2b^2 P_n}{n^2 \pi^2 \sinh \frac{n\pi c_1}{b}} \left(\cosh \frac{n\pi c_1}{b} - 1 \right) \dots [30]$$

Again, for region (2)

$$W_2 = \int_0^b \int_{-c_2}^0 - \sum_{n=1,3,5,\dots}^{\infty} \frac{P_n}{\sinh \frac{n\pi c_2}{b}} \sin \frac{n\pi z}{b} \sinh \frac{n\pi x}{b} \, dx \, dz$$

$$= \int_0^b \sum_{n=1,3,5,\dots}^{\infty} \frac{b}{n\pi} \frac{P_n}{\sinh \frac{n\pi c_2}{b}} \left(\cosh \frac{n\pi c_2}{b} - 1 \right) \sin \frac{n\pi z}{b} \, dz$$

$$\therefore W_2 = \sum_{n=1,3,5,\dots}^{\infty} \frac{2b^2 P_n}{n^2 \pi^2 \sinh \frac{n\pi c_2}{b}} \left(\cosh \frac{n\pi c_2}{b} - 1 \right) \dots [31]$$

The total load, $W = W_1 + W_2$

Then

$$W = \sum_{n=1,3,5,\dots}^{\infty} \frac{2b^2 P_n}{n^2 \pi^2} \left(\frac{\cosh \frac{n\pi c_1}{b} - 1}{\sinh \frac{n\pi c_1}{b}} + \frac{\cosh \frac{n\pi c_2}{b} - 1}{\sinh \frac{n\pi c_2}{b}} \right)$$

By use of standard relations for the hyperbolic functions, W can be rewritten as

$$W = \sum_{n=1,3,5,\dots}^{\infty} \frac{2b^2 P_n}{n^2 \pi^2} \left(\tanh \frac{n\pi c_1}{2b} + \tanh \frac{n\pi c_2}{2b} \right)$$

If P_n from Equation [29] is substituted, the load is obtained as

$$W = \frac{48\mu U b^3 (h_2 - h_1)}{\pi^4} \sum_{n=1,3,5,\dots}^{\infty} \frac{1}{n^4} \frac{\tanh \frac{n\pi c_1}{2b} + \tanh \frac{n\pi c_2}{2b}}{h_1^3 \coth \frac{n\pi c_1}{b} + h_2^3 \coth \frac{n\pi c_2}{b}} \dots [32]$$

The foregoing solution applies to a rectangular slider having uniform rectilinear motion. This simplified problem is a logical first step because the mathematical work is more likely to be soluble. The result is also useful for comparison with the results of Michell's solution for the inclined flat-plate bearing. However, a more practical solution is possible, and this will be given before discussing the implications of Equation [32].

STEPPED SECTORIAL SLIDER

Instead of the stepped rectangular slider consider a stepped sectorial slider as shown in Fig. 4.

FIG. 4

With such a configuration, it is natural to adopt plane polar co-ordinates. Laplace's equation, that is Equation [18], in polar co-ordinates becomes

$$\frac{\partial^2 p}{\partial r^2} + \frac{1}{r^2} \frac{\partial^2 p}{\partial \theta^2} + \frac{1}{r} \frac{\partial p}{\partial r} = 0 \dots [33]$$

A new variable is introduced by letting $r = r_1 e^\rho$, where r_1 is the inner radius of the sector and ρ is the new variable. Clearly, when

$$r = r_1, \rho = 0, \text{ and when } r = r_2, \rho = \rho_2 = \log r_2/r_1$$

If the new variable ρ is substituted, Equation [33] becomes

$$\frac{\partial^2 p}{\partial \rho^2} + \frac{\partial^2 p}{\partial \theta^2} = 0 \dots [34]$$

The solution now proceeds on almost exactly similar lines to the rectangular case. It is assumed that the pressure on the common boundary is given by

$$p = \sum_n P_n \sin \frac{n\pi \rho}{\rho_2} \dots [35]$$

The question of what values of n are to be used in the summation is left open at this stage. It is fairly evident from the physical situation that the curve will not be symmetrical.

As in the previous cases, it is convenient to use two co-ordinate systems. For region (1) the zero of θ is taken through the trailing

edge of the slider. For region (2) the zero of θ is moved forward to the leading edge of region (2). The equations for pressure in regions (1) and (2) are obtained by the same methods as for the rectangular case and are identical in form. They are as follows:

For region (1)

$$p = \sum_n \frac{P_n}{\sinh \frac{n\pi \theta_1}{\rho_1}} \sin \frac{n\pi \rho}{\rho_1} \sinh \frac{n\pi \theta}{\rho_1} \dots [36]$$

For region (2)

$$p = - \sum_n \frac{P_n}{\sinh \frac{n\pi \theta_2}{\rho_2}} \sin \frac{n\pi \rho}{\rho_2} \sinh \frac{n\pi \theta}{\rho_2} \dots [37]$$

To calculate the Fourier coefficient P_n , it is necessary to use the rate-of-flow relation given by Equation [3a]. But now this must be expressed in polar co-ordinates. The rate of flow in the tangential direction is then

$$-q\theta = -\frac{r\omega h}{2} - \frac{h^3}{12\mu r} \frac{\partial p}{\partial \theta} \dots [38]$$

where ω is the rotational speed of the moving element.

On making the substitution $r = r_1 e^\rho$ this equation for flow becomes

$$-q\theta = -\frac{\omega r_1 e^\rho h}{2} - \frac{h^3}{12\mu r_1 e^\rho} \frac{\partial p}{\partial \theta} \dots [39]$$

The evaluation of $\partial p / \partial \theta$ at the common boundary is exactly the same as for the rectangular case and need not be repeated. The equality of the rate of flow out of region (2) into region (1) at any point on the common boundary, therefore, can be written down directly from Equation [39] and by analogy with Equation [27]

$$-\frac{\omega r_1 e^\rho h_1}{2} - \frac{h_1^3}{12\mu r_1 e^\rho} \sum_n \frac{n\pi}{\rho_2} P_n \coth \frac{n\pi \theta_1}{\rho_2} \sin \frac{n\pi \rho}{\rho_2} = -\frac{\omega r_1 e^\rho h_2}{2} + \frac{h_2^3}{12\mu r_1 e^\rho} \sum_n \frac{n\pi}{\rho_2} P_n \coth \frac{n\pi \theta_2}{\rho_2} \sin \frac{n\pi \rho}{\rho_2}$$

which can be rewritten as

$$\sum_n \frac{n\pi}{\rho_2} P_n \left(h_1^3 \coth \frac{n\pi \theta_1}{\rho_2} + h_2^3 \coth \frac{n\pi \theta_2}{\rho_2} \right) \sin \frac{n\pi \rho}{\rho_2} = 6\mu \omega r_1^2 e^{2\rho} (h_2 - h_1) \dots [40]$$

The factor $e^{2\rho}$ can be expanded in a Fourier series as follows

$$e^{2\rho} = \sum_n K_n \sin \frac{n\pi \rho}{\rho_2}$$

$$K_n = \frac{2}{\rho_2} \int_0^{\rho_2} e^{2\rho} \sin \frac{n\pi \rho}{\rho_2} d\rho$$

Upon evaluation of this integral, K_n is given for all integral values of n as

$$K_n = \frac{2n\pi[(-1)^{n+1}e^{2\rho_1} + 1]}{n^2\pi^2 + 4\rho_1^2} \dots \dots \dots [41]$$

Equation [40] can be written

$$\sum_n \frac{n\pi}{\rho_2} P_n \left(h_1^3 \coth \frac{n\pi\theta_1}{\rho_2} + h_2^3 \coth \frac{n\pi\theta_2}{\rho_2} \right) \sin \frac{n\pi\rho}{\rho_2} \\ = \sum_n 6\mu\omega r_1^2 (h_2 - h_1) K_n \sin \frac{n\pi\rho}{\rho_2} \dots \dots \dots [42]$$

This can be solved for P_n and gives, when K_n is substituted from Equation [41]

$$P_n = \frac{12\mu\omega r_1^2 \rho_2 [(-1)^{n+1}e^{2\rho_1} + 1] (h_2 - h_1)}{(n^2\pi^2 + 4\rho_2^2) \left[h_1^3 \coth \frac{n\pi\theta_1}{\rho_2} + h_2^3 \coth \frac{n\pi\theta_2}{\rho_2} \right]} \dots [43]$$

The pressure can now be found at any point of region (1) or (2) by use of Equations [36] and [37]. But, as in the rectangular case, the load is of more interest and is readily obtained by integrating over the areas. As before, W_1 will refer to the load supported by region (1), and W_2 will refer to the load supported by region (2). Then

$$W_1 = \int_{r_1}^{r_2} \int_0^{\theta_1} p r d\theta dr \\ = \int_0^{\rho_1} \int_0^{\theta_1} p r_1 e^{\rho} d\theta r_1 e^{\rho} d\rho \\ \therefore W_1 = \int_0^{\rho_1} \int_0^{\theta_1} \sum_n \frac{r_1^2 P_n}{\sinh \frac{n\pi\theta_1}{\rho_2}} e^{2\rho} \sin \frac{n\pi\rho}{\rho_2} \sinh \frac{n\pi\theta}{\rho_2} d\rho d\theta \\ = \int_0^{\rho_1} \sum_n \frac{r_1^2 P_n}{\sinh \frac{n\pi\theta_1}{\rho_2}} \frac{\rho_2}{n\pi} \left(\cosh \frac{n\pi\theta_1}{\rho_2} - 1 \right) e^{2\rho} \sin \frac{n\pi\rho}{\rho_2} d\rho \\ = \sum_n \frac{r_1^2 P_n}{\sinh \frac{n\pi\theta_1}{\rho_2}} \frac{\rho_2}{n\pi} \left[\frac{e^{2\rho} \left(-\frac{n\pi}{\rho_2} \cos n\pi \right) + \frac{n\pi}{\rho_2}}{\left(\frac{n^2\pi^2}{\rho_2^2} + 4 \right)} \right] \\ \left(\cosh \frac{n\pi\theta_1}{\rho_2} - 1 \right)$$

Since n may be even or odd, this can be written as

$$W_1 = \sum_n \frac{r_1^2 P_n [(-1)^{n+1}e^{2\rho_1} + 1]}{\left(\frac{n^2\pi^2}{\rho_2^2} + 4 \right) \sinh \frac{n\pi\theta_1}{\rho_2}} \left(\cosh \frac{n\pi\theta_1}{\rho_2} - 1 \right) \dots [44]$$

In the same way W_2 is given as follows

$$W_2 = \int_0^{\rho_2} \int_{-\theta_2}^0 \sum_n \frac{P_n}{\sinh \frac{n\pi\theta_2}{\rho_2}} e^{2\rho} \sin \frac{n\pi\rho}{\rho_2} \sinh \frac{n\pi\theta}{\rho_2} d\rho d\theta \\ \therefore W_2 = \sum_n \frac{r_1^2 P_n [(-1)^{n+1}e^{2\rho_1} + 1]}{\left(\frac{n^2\pi^2}{\rho_2^2} + 4 \right) \sinh \frac{n\pi\theta_2}{\rho_2}} \left(\cosh \frac{n\pi\theta_2}{\rho_2} - 1 \right) [45]$$

$$\therefore W = \sum_n \frac{r_1^2 P_n [(-1)^{n+1}e^{2\rho_1} + 1]}{\left(\frac{n^2\pi^2}{\rho_2^2} + 4 \right)} \left(\frac{\cosh \frac{n\pi\theta_1}{\rho_2} - 1}{\sinh \frac{n\pi\theta_1}{\rho_2}} + \frac{\cosh \frac{n\pi\theta_2}{\rho_2} - 1}{\sinh \frac{n\pi\theta_2}{\rho_2}} \right)$$

Placing in the value of P_n from Equation [43] and making use of the standard hyperbolic relations, W can be written as

$$W = 12\mu\omega r_1^2 \rho_2^3 (h_2 - h_1) \sum_n \left[\frac{(-1)^{n+1}e^{2\rho_1} + 1}{n^2\pi^2 + 4\rho_2^2} \right] \left[\frac{\tanh \frac{n\pi\theta_1}{2\rho_2} + \tanh \frac{n\pi\theta_2}{2\rho_2}}{h_1^3 \coth \frac{n\pi\theta_1}{\rho_2} + h_2^3 \coth \frac{n\pi\theta_2}{\rho_2}} \right] \\ \text{But } e^{2\rho_1} = (r_2/r_1)^2, \text{ and } \rho_2 = \log r_2/r_1 \\ \therefore W = 12\mu\omega \left(\log \frac{r_2}{r_1} \right)^3 (h_2 - h_1) \sum_n \left[\frac{(-1)^{n+1}r_2^2 + r_1^2}{n^2\pi^2 + 4 \left(\log \frac{r_2}{r_1} \right)^2} \right] \\ \times \left[\frac{\tanh \frac{n\pi\theta_1}{\log \left(\frac{r_2}{r_1} \right)^2} + \tanh \frac{n\pi\theta_2}{\log \left(\frac{r_2}{r_1} \right)^2}}{h_1^3 \coth \frac{n\pi\theta_1}{\log \frac{r_2}{r_1}} + h_2^3 \coth \frac{n\pi\theta_2}{\log \frac{r_2}{r_1}}} \right] \dots \dots \dots [46]$$

It is now a fairly easy matter to obtain the relations for the quantity of lubricant passing through the bearing and also to find the force and torque on the bearings. Since these are matters of secondary importance only the final formulas will be given.

FORCE REQUIRED TO MOVE FLAT ELEMENT IN RECTANGULAR BEARING

For the rectangular bearing, the force required to move the flat element is given by

$$F = \mu U b \left(\frac{c_1}{h_1} + \frac{c_2}{h_2} \right) + \frac{24 \mu U b^2 (h_2 - h_1)^2}{\pi^3} \sum_{n=1,3,5,\dots} \frac{1}{n^3 \left(h_1^3 \coth \frac{n\pi c_1}{b} + h_2^3 \coth \frac{n\pi c_2}{b} \right)} \dots \dots [47]$$

The quantity entering at the leading edge is

$$Q_2 = \frac{U h_2 b}{2} - \frac{4 U b h_2^2 (h_2 - h_1)}{\pi^2} \sum_{n=1,3,5,\dots} \frac{1}{n^2 \sinh \frac{n\pi c_2}{b}} \left(\frac{1}{h_1^3 \coth \frac{n\pi c_1}{b} + h_2^3 \coth \frac{n\pi c_2}{b}} \right) \dots \dots [48]$$

The quantity leaving at the trailing edge is

$$Q_1 = \frac{U h_1 b}{2} + \frac{4 U b h_1^2 (h_2 - h_1)}{\pi^2} \sum_{n=1,3,5,\dots}^{\infty} \frac{1}{n^2 \sinh \frac{n\pi c_1}{b}} \left(\frac{1}{h_1^3 \coth \frac{n\pi c_1}{b} + h_2^3 \coth \frac{n\pi c_2}{b}} \right) \dots [49]$$

The side leakage can be obtained by difference.

For the sector bearing the corresponding quantities are as follows:

The torque required to turn the bearing is given by

$$T = \frac{\mu \omega (r_2^4 - r_1^4)}{4} \left(\frac{\theta_1}{h_1} + \frac{\theta_2}{h_2} \right) + 6\pi (h_2 - h_1)^2 \mu \omega \left(\log \frac{r_2}{r_1} \right)^2 \sum_{n=1,3,5,\dots}^{\infty} \left[\frac{(-1)^{n+1} r_2^2 + r_1^2}{n^2 \pi^2 + 4 \left(\log \frac{r_2}{r_1} \right)^2} \right] \left(\frac{1}{h_1^3 \coth \frac{n\pi \theta_1}{\log \frac{r_2}{r_1}} + h_2^3 \coth \frac{n\pi \theta_2}{\log \frac{r_2}{r_1}}} \right) \dots [50]$$

The lubricant entering at the leading edge is given by

$$Q_2 = \frac{\omega h_2 (r_2^2 - r_1^2)}{4} - 2\omega \left(\log \frac{r_2}{r_1} \right) h_2^2 (h_2 - h_1) (r_2^2 - r_1^2) \sum_{n=1,3,5,\dots}^{\infty} \frac{1}{\left[n^2 \pi^2 + 4 \left(\log \frac{r_2}{r_1} \right)^2 \right] \sinh \frac{n\pi \theta_2}{\log \frac{r_2}{r_1}} \left(h_1^3 \coth \frac{n\pi \theta_1}{\log \frac{r_2}{r_1}} + h_2^3 \coth \frac{n\pi \theta_2}{\log \frac{r_2}{r_1}} \right)} \dots [51]$$

The lubricant leaving at the trailing edge is given by

$$Q_1 = \frac{\omega h_1 (r_2^2 - r_1^2)}{4} + 2\omega \left(\log \frac{r_2}{r_1} \right) h_1^2 (h_2 - h_1) (r_2^2 - r_1^2) \times \sum_{n=1,3,5,\dots}^{\infty} \frac{1}{\left[n^2 \pi^2 + 4 \left(\log \frac{r_2}{r_1} \right)^2 \right] \sinh \frac{n\pi \theta_1}{\log \frac{r_2}{r_1}} \left(h_1^3 \coth \frac{n\pi \theta_1}{\log \frac{r_2}{r_1}} + h_2^3 \coth \frac{n\pi \theta_2}{\log \frac{r_2}{r_1}} \right)} \dots [52]$$

The side leakage can be obtained by difference.

It will be observed that the series in Equations [32] and [46] converge very rapidly. For a square bearing a single term gives a result within 1 or 2 per cent of the actual value. The series for the sectorial bearing will converge somewhat less rapidly. For a "square" shape (i.e., the mean arc length equal to the radial depth), a satisfactory value can be obtained with 3 or 4 terms. In both cases the convergence becomes less rapid as the bearing becomes wider with respect to its length.

Equations [12], [32], and [46] give the load that can be supported on a bearing having the stepped-film shape. The conditions for a maximum of Equation [12] are fairly easily found, and this maximum is given in Equation [16]. The same device if applied to Equations [32] and [46] leads to great complication, and the method of trial is easier. It is found that the proportions for maximum load when side leakage is neglected are not the best proportions for a bearing of finite width. The values for the case of no side leakage were, $h_2 = 1.866 h_1$ and $c_2 = 2.549 c_1$. For a square bearing, it is found that the best values are, approximately, $h_2 = 1.7 h_1$ and $c_2 = 1.2 c_1$. However, the load capacity is not very sensitive to changes in the vicinity of these values.

COMPARISON OF LOADS WITH MICHELL FLAT-PLATE BEARING LOADS

It is interesting to compare the load given by Equation [32] for a square bearing to that given by Michell for an inclined flat plate. If the proportions given in the foregoing for the case of no side leakage are used, the bearing is about 6 per cent less effective than

the inclined-plane bearing. But if the best proportions are used it is about 3 per cent more effective. The 29 per cent improvement, obtained when side leakage is neglected, is reduced so that the bearing is only slightly better than the inclined-plane bearing in this respect. The side-leakage effect is no doubt aggravated because the large film thickness extends into the highest-pressure region, and thus offers an easier means of escape for the lubricant. If the bearing is made wider it gradually gains on the inclined-plane bearing and tends to approach the value given by Equation [16]. If it is made narrower it gradually gets less than the inclined-plane bearing.

A way in which the bearing could be improved to some extent

would be to make the stepped element as shown in Fig. 5. Such a shape would add to the mathematical difficulties and would be somewhat harder to produce unless it were etched. Probably the matter of increasing the capacity is not very important in practice as the loads that arise are already being taken by tilting-

Fig. 5

block bearings of reasonable size, and it has been shown that these bearings are not quite as effective as the stepped arrangement.

An interesting conclusion can be drawn from Equations [32] and [46] by inspection. It will be recalled that the hyperbolic tangent approaches unity for quite small values of its argument. For example, $\tanh 3 = 0.99505$ and $\tanh 5 = 0.9991$. It is clear that if all other conditions are held constant, the load capacity is not increased appreciably by an increase in the length of the bearing beyond a certain point. This has particular significance in the case of a sector bearing because here there is a limit to the angle that can be subtended by a sector, viz., 360-deg. Thus if the ratio of outer to inner radii is 2, a pair of 180-deg sectors would

support almost exactly twice the load that could be carried by a single 360-deg bearing, other conditions being held constant. Also, three 120-deg sectors would be almost exactly 3 times as effective as a single 360-deg bearing (oil passages are neglected for simplicity in discussion; their influence would be small for large sectors). Obviously, there is a point at which this process of division would start to give a diminishing return. This could be fairly easily determined if the sector radii and oil-passage space were prescribed as well as the conditions of speed and viscosity. The matter is a little complicated by the fact that for each new angular condition the ratios of θ_2 to θ_1 and h_2 to h_1 will change for best conditions. However, a very good result would be obtained by holding these ratios constant at some reasonable value until the best number of sectors was found, and then making a more careful calculation in this vicinity to find best conditions.

CONCLUSION

The stepped-bearing arrangement has a good deal to recommend it in practice although there are two matters which are not especially in its favor. The bearing does not have any great advantage in load capacity over the inclined-plane bearing, and it is restricted to one direction of rotation. Offsetting these matters is its great constructional simplification over the tilting-block bearing, or even over those bearings in which the taper is machined into one of the elements. In addition, the fairly simple explicit equations for the load offer some advantage in design where the influence of each parameter is fairly easy to see and can be checked quite readily. It is true that viscosity has been taken as constant, and this can be quite misleading. However, there are ways of estimating the change in viscosity through the bearing, and a mean value seems to give fairly good results. In this respect the solution is no worse than others. It should be possible to apply this bearing to a great many thrust problems and in particular to those cases where space considerations are of importance.

Some experiments of a semiquantitative nature have been made with bearing models. It is well known that precise results by this means are rather difficult to obtain. However, reasonable agreement was found. An air-lubricated model in which the step height, i.e., $(h_2 - h_1)$, is about 0.00005 in. has been made and is entirely successful. Lord Rayleigh describes a simple test he made of the scheme in his paper.³

Discussion

J. R. MENKE.³ The author has presented a useful extension of Lord Rayleigh's calculations and has done a service in calling more general attention to this relatively unappreciated paper.⁴ The writer's attention was drawn to the paper in 1943-1944 by John E. Viscardi and Mayo D. Hersey with a practical result.

The author remarks in his discussion upon the behavior of the hyperbolic tangent terms in Equations [32] and [46]. This behavior is hardly surprising in the physical sense, indicating only that side leakage as usual reduces the advantage of increasing length in long, "thin" (i.e., not wide) bearings.

Fig. 5 of the paper indicates an interesting improvement, and one wonders about the estimated extent of this improvement. Is a large part of the potential 29 per cent gain over inclined-plate bearings feasible? Tests on this point should prove worth while.

The bearing examined is evidently simple in two respects; it can be readily understood and it can be manufactured cheaply. With such advantages and its indicated performance one might expect some industrial acceptance after these thirty-odd years since Lord Rayleigh's paper.

Density-Pressure Relationships for Two Low-Viscosity Dimethyl Siloxanes

By S. R. GUNST,¹ PITTSBURGH, PA.

An instrument used to determine liquid compressibilities is described² as is its use in the determination of density versus pressure for hexamethyldisiloxane and octamethyltrisiloxane. Results at pressures to 10,000 psi, and at temperatures to 200 F for the hexamethyldisiloxane and to 300 F for the octamethyltrisiloxane are shown. The densities are precise within 0.3 per cent.

INTRODUCTION

THE dimethyl siloxanes are members of the group frequently called silicone liquids (1, 2, 3).³ They are heat-stable, chemically inert compounds (4). Their stability and small viscosity change with temperature suggest their potential excellence as viscometer-calibration standards, the objective which prompted this investigation.

In the rolling-ball viscometer (5), an instrument used for the determination of absolute viscosities of fluids at elevated pressures, the densities of the fluids under test conditions must be ascertained. This investigation was undertaken to determine the density-pressure relationships for two dimethyl siloxanes.

For mineral oils the density-pressure equation of Dow and Fink (6) has given satisfactory results; but for silicone liquids, in so far as is known, little experimental work from which such relations may be derived has been published (7, 8). Although the results of this investigation on only two silicone liquids are insufficient to yield a density-pressure equation for all silicones, they should be useful for the liquids tested, and subsequent work may lead to a density-pressure equation for silicones corresponding to that of Dow and Fink for mineral oils.

DESCRIPTION OF APPARATUS

For this investigation it was necessary to design and build an instrument for making measurements from which the compressibility of a liquid could be computed. A search of the literature (9, 10, 11) showed the many difficulties and attendant uncertainties experienced by the early investigators, and it is believed the instrument embraces the best principles of design known at this time. The pressure joints are self-sealing; the expansion of the pressure vessel is irrelevant; the test liquid is contained in a thin-walled, commercially available brass bellows, whose spring constant and bulk compression are negligibly small, and whose free end is unhampered by any sliding surfaces with their attendant friction; the instrument demands no calibration with a liquid whose compressibility is known; and it is continuously reading

so that a single charge of sample liquid within the bellows suffices for all pressures and temperatures encountered in this investigation.

A cross-sectional sketch of the instrument, hereafter referred to as the "compressibility meter," is shown in Fig. 1. The brass bellows 1, soldered to brass plugs 2 and 3, is filled with the test-liquid sample. The sample is trapped in the bellows by a steel taper pin 4, and a steel contact plate 5, which seals by compressing an aluminum gasket 6. The upper end of the bellows is held fixed by threading the upper plug 2 into the steel end plate 7, which is positioned in the steel pressure housing 8 by a steel end screw 9. A bakelite bushing 10, electrically insulates the brass bellows housing 11, with its brass micrometer spider 12, and steel micrometer screw 13, from the bellows. Adjustment of the micrometer screw is accomplished by turning the graduated brass knob 14. This turns a steel shaft 15, whose three steel fingers 16, engage the bakelite fluted coupling 17, attached to the micrometer screw. A steel spring 18, takes up the micrometer-screw backlash, and a thrust bearing 19, takes the load on the head of the shaft 15, resulting from internal pressure applied hydraulically inside the

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society. Paper No. 49-A-91.

pressure housing through the inlet 20. Three equally spaced annular slots in the top plate of the jacket 21, permit the admission of liquid into the jacket, and the immersion in this liquid of a strip heater, a stirrer, a thermoregulator, and a thermometer. Three steel legs 22, support the compressibility meter on a suitable workbench. Synthetic-rubber O-rings 23 and 24, serve as self-sealing gasket and packer, respectively, and a nylon bushing 25, serves both as a self-sealing gasket and an electrical insulator for the contact pin 26. A fiberglass-insulated wire 27, connects the contact pin to the bellows housing 11.

When the micrometer screw 13, is made to contact the contact plate 5, electrical connection is effected from the contact pin 26, to the bellows housing to the micrometer screw to the bellows to the pressure housing. Thus a suitable electrical indicator connected between the contact pin and the pressure housing will indicate contact between the contact plate and the micrometer screw. The micrometer screw has a major diameter of $1/4$ in. and 40 threads per inch. One turn advances the screw 0.025 in. Fifty graduations on the circumference of the knob 14, permit direct readings corresponding to a micrometer-screw advance of 0.0005 in. and estimations to 0.0001 in. With a suitably sensitive indicator, therefore, the variation in bellows length can be measured to 0.0001 in.

Hydraulic pressure, applied by means of a free-piston gage (12), commonly called a "dead-weight tester," is transmitted to all parts inside the pressure housing—to the bellows via six axial holes in the micrometer spider 12, and four axial slots (not shown in Fig. 1) in the bellows housing 11, and to the top of the taper pin 4, sealing the top of the bellows via four radial holes in the collar of the end plate 7. The application of pressure to the outside of the bellows compresses the test-liquid sample within the bellows and results in a decrease in bellows length, which can be measured as previously indicated.

In order to decrease heat loss, asbestos steam-pipe insulation 28, $1\frac{1}{2}$ in. thick, blankets the compressibility meter so that only the legs, the knob, the pressure inlet, and parts of the thermometer and temperature-control apparatus are exposed.

ANALYTICAL CONSIDERATIONS

Measurements of a variation in bellows length can be used to calculate the change in density of a test-liquid sample. For a mass m of liquid occupying a volume V the liquid density is given by

$$\rho = m/V \dots \dots \dots [1]$$

With atmospheric-pressure conditions denoted by a subscript 0, an isothermal change in density because of a change in pressure is given by

$$\Delta\rho = \rho - \rho_0 = (m/V) - (m/V_0) = \frac{m(V_0 - V)}{VV_0} \dots \dots [2]$$

Let $V = V_0 + \Delta V$ and Equation [2] becomes

$$\begin{aligned} \Delta\rho &= -\frac{m\Delta V}{V_0(V_0 + \Delta V)} = -\frac{\rho_0}{(V_0/\Delta V) + 1} \\ &= -\frac{\rho_0}{(m/\rho_0\Delta V) + 1} \dots \dots [3] \end{aligned}$$

Tests to determine the change in bellows volume with change in bellows length at constant temperature and pressure showed that $\Delta V = A\Delta L$, where ΔL is the change in bellows length and A is a constant, obviously the effective cross-sectional area of the inside of the bellows. Equation [3] can therefore be written

$$\Delta\rho = -\frac{\rho_0}{(m/\rho_0 A\Delta L) + 1} \dots \dots \dots [4]$$

from which the isothermal change in density resulting from a change in pressure can be calculated if all quantities on the right are known.

A graph of $\Delta\rho$ or ρ versus pressure p can be used to calculate the isothermal compressibility k of a liquid if desired. With isothermal conditions designated by a subscript T , k is given by

$$\begin{aligned} k &= -\frac{1}{V} \left(\frac{\partial V}{\partial p} \right)_T = -\frac{1}{V} \left(\frac{\partial \rho}{\partial p} \right)_T \left(\frac{\partial V}{\partial \rho} \right)_T = \frac{1}{\rho} \left(\frac{\partial \rho}{\partial p} \right)_T \\ &= \frac{1}{(\rho_0 + \Delta\rho)} \left(\frac{\partial \rho}{\partial p} \right)_T \dots \dots [5] \end{aligned}$$

Since the slope of the graph of $\Delta\rho$ or ρ versus pressure at any pressure is $(\partial\rho/\partial p)_T$, readily obtainable by graphical differentiation, k can be calculated.

TEST METHODS AND RESULTS

Preliminary investigations were made in order to establish methods for temperature measurement and control, to determine the effective cross-sectional area of the bellows, and to ascertain the effect of cubic compression of the various parts of the compressibility meter on bellows length measurements. The latter was found to be negligible.

The two liquids investigated were hexamethyldisiloxane and octamethyltrisiloxane, referred to by one manufacturer, the Dow-Corning Corporation, as DC-200 silicone fluid, viscosity 0.65 centistoke at 25 C, and DC-200 silicone fluid, viscosity 1.0 centistoke at 25 C, respectively. Equation [4] was used to calculate change in density $\Delta\rho$ for various temperatures and pressures.

1 The density ρ_0 :

The density ρ_0 at atmospheric pressure and test temperature was obtained from hydrometer tests by chemists at the author's laboratory and checked with the results of Hurd (3).

2 Effective bellows cross-sectional area A :

The cross-sectional area A of the bellows was found to be essentially independent of bellows length and pressure. The value of A of 0.764 sq in. determined by test at 75 F was used and corrected for thermal expansion, using a handbook value for the expansivity of brass.

3 The mass m of liquid filling the bellows:

Anticipated difficulties in filling the bellows with a test sample of liquid to the essential exclusion of air were easily overcome. The bellows assembly, with the taper pin removed, was immersed in an oil bath until only $1/8$ in. of the bellows taper-pin plug was exposed. The bath was maintained at a temperature above the maximum test temperature of a specific test liquid. A long-necked eyedropper inserted through the taper-pin hole was used to fill the bellows with test liquid. A glass stirring rod was used to agitate the bellows convolutions in order to rid them of air bubbles. The bellows was kept constantly filled by means of the eyedropper. After all evidence of bubbling through the taper-pin hole had ceased, the taper pin was driven into the taper-pin hole, thus sealing the test liquid within the bellows.

The mass m of test-sample liquid is the difference between the filled-bellows mass and empty-bellows mass obtained by the double massing method (13) with appropriate corrections for air buoyancy. The bellows assembly was carefully cleaned and dried prior to all mass determinations.

Only one filling of the bellows was necessary for all tests made

on each of the liquids and their corresponding masses were as follows:

Hexamethyldisiloxane mass $m = 13.630$ grams
Octamethyltrisiloxane mass $m = 13.575$ grams

4 Isothermal change in bellows length ΔL versus pressure:

Measurements of variation in bellows length at pressure intervals of 100 psi from 0 to 500 psi (gage), and at intervals of 500 psi from 500 to 10,000 psi (gage) were made for the two liquids at the following temperatures:

FIG. 2 MEASURED VARIATION IN BELLOWS LENGTH FROM ARBITRARY ZERO AT EACH TEMPERATURE VERSUS GAGE PRESSURE FOR HEXAMETHYLDISILOXANE

Hexamethyldisiloxane 76.0, 100.0, 149.9, 200.0 F
Octamethyltrisiloxane 77.5, 100.0, 150.0, 200.0, 250.0, 300.0 F

(At an absolute pressure of 760 mm Hg, the liquids have the following approximate boiling points: Hexamethyldisiloxane, 211 F; octamethyltrisiloxane, 306 F).

The results of the tests for hexamethyldisiloxane, the dimer, are graphed in Fig. 2, and for octamethyltrisiloxane, the trimer, in Fig. 3.

COMPUTED RESULTS

Smoothed values of change in bellows length ΔL versus gage pressure, taken from the graphs in Figs. 2 and 3, are shown in Tables 1 and 2, as are the corresponding values of change in test-liquid density $\Delta \rho$ calculated from Equation [4]. The box headings of the tables bear appropriate values of the test-liquid temperature, the bellows cross-sectional area A , and the test-liquid density ρ_0 at atmospheric pressure. Graphs of test-liquid density ρ as a function of gage pressure are presented in Figs. 4 and 5, from which the density for any pressure can be read. Moreover, isobaric graphs of ρ versus temperature can readily be constructed from the graphs in Fig. 4 or 5, with which the density at any temperature from 75 to 200 F for the dimer, and from 75 to 300 F for the trimer and at any gage pressure from 0 to 10,000 psi for either can be determined.

Check tests confirmed results within experimental error.

The isothermal compressibilities, computed according to Equation [5], are shown in Figs. 6 and 7.

CONCLUSION

Calculations showed that the densities of the two dimethyl siloxanes were determined with a probable error no greater than 0.0018 gram per cu cm over a pressure range of 10,000 psi and at various temperatures.

ACKNOWLEDGMENT

The author is indebted to Mr. Paul G. Exline, formerly Section Engineer of Gulf Research and Development Company, for early suggestions concerning the problem and equipment design features; to Dr. David Halliday of the University of Pittsburgh, and to Mr. R. J. S. Pigott, Director of Engineering of Gulf Research and Development Company, for sponsoring this investigation; and to Dr. Paul D. Foote, Executive Vice-President and Director of Gulf Research and Development Company, for permission to disclose the results.

Discussion

P. W. BRIDGMAN.⁴ This is an interesting and ingenious adaptation of the sylphon method of measuring compressibilities which the writer developed a number of years ago⁵ for use over a wider pressure range. For the purpose at present in view (determination of the density correction in rolling-ball viscometers used under pressure), and within the range of accuracy claimed (0.3 per cent on the densities), the apparatus seems entirely adequate. A check on this is afforded by comparing the author's results with those of the writer⁶ for the same two liquids at room temperature. After making corrections for slight differences of temperature, and expressing the results as fractional changes of initial volume instead of initial density, the writer finds for the author's value of $\Delta V/V_0$ at approximately 24°C at a pressure of 7110 psi (500 kg per sq cm) for hexamethyldisiloxane and octamethyltrisiloxane, respectively, 0.0552 and 0.0597. These values may be compared with the writer's of 0.0568 and 0.0586, respectively. The agreement is thus well within the claimed error, which would correspond to 0.003.

It would seem that the method should be capable of considerably greater accuracy than claimed, for 0.3 per cent on the absolute density is not high. It is to be regretted that the author did not take the opportunity to find the probable limits of accuracy. To do this, comparison with measurements by other methods is necessary, because there can be no question but there are intrinsic sources of error in the sylphon method owing to internal strains in the metal of the sylphon, which has been subject to very great deformations in the forming process. It may well be that the accuracy would prove great enough to justify use of the apparatus in making measurements of the compression of liquids for their own sake, as demanded in work on the equation of state of liquids. This apparatus has an especial advantage for such use in the wide temperature range that can be covered easily.

R. B. DOW.⁷ This paper represents a valuable contribution to the means available for calibrating high-pressure viscometers over the moderate pressure range of 10,000 psi. The writer and his collaborators have previously used a series of carefully chosen lubricating oils of such densities and viscosities as required to give suitable calibration curves for the rolling-ball type of viscometer. The present choice of silicone liquids is to be preferred chiefly because of the ready availability of a standard product, although the stability and small temperature coefficients of viscosity are valid reasons for considering them more suitable than oils. The author's results should be useful for all workers in this field who will welcome all advances toward standardization.

The compressibility meter is a well-designed and simple device which has been adapted from the sylphon piezometer of Prof. P. W. Bridgman. The techniques of measurement differ only in the method of measuring changes of length, Bridgman using changes of resistance of a fine manganin slide wire attached

directly to the top of the siphon instead of direct readings on a micrometer screw. The siphon piezometer has several obvious points of superiority over the old type of piston displacement in a pressure cylinder containing the test liquid. For the present pressure range the use of a micrometer is both direct and convenient since it can be used with a simple pressure seal which would not suffice at much higher pressures.

In respect to the corrections employed in the present work, it appears that the length of the screw was not corrected for possible changes due to changes of pressure and temperature. The correction for pressure would be negligible except at the highest pressure used, at which it would be of a magnitude about comparable with the accuracy of measurement. The correction for temperature, on the other hand, appears to be well within the accuracy of measurement between the limits of 76 and 200 F.

The value of the results are enhanced by the fact that several temperatures were used. It is suggested that, in addition to the value of 100 F, it would be desirable to have data at 130 and 210 F since the viscosities of oils are commonly measured at these temperatures.

P. G. EXLINE.⁸ This paper describes an instrument capable of determining liquid densities and compressibilities with a higher order of accuracy and with much greater convenience than has hitherto been obtainable. A single filling of the instrument suffices for all determinations over the allowable temperature and pressure range of the instrument. The pressure and temperature ranges covered by the author were rather arbitrarily limited by the materials tested and by the pressure-measuring instruments used. It would add to the value of the paper if a reasonable estimate could be given of the pressure and temperature limits to which the instrument could be used.

Although the author reports unusually high accuracy for determinations of this nature, the writer believes that an additional correction could well have been made. In determining liquid compressibilities in a vessel in which the internal pressure equals the external pressure, the direct observations yield the difference between the compressibility of the liquid and that of the material of the vessel.⁹ The fact that in the author's instrument the liquid is contained in a vessel capable of free axial elongation does not alter the situation, as the radius of the bellows is reduced by the pressure, and the brass bellows housing carrying the micrometer nut will be shortened. At the most, this correction would alter the reported values of $\Delta\rho$ by slightly under 1 per cent.

In calculating compressibilities from the density data the author has selected a definition of K which does not yield easily usable values, a mistake of which the writer has also been guilty.¹⁰

If the compressibility is defined as

$$K = \frac{1}{V_0} \frac{(V_0 - V)}{P}$$

where V is the volume at pressure P and V_0 is the volume at zero pressure, it is much more easily applied to numerical computations. In this case the compressibility can be expressed as a function of ρ as follows

$$K = \frac{\Delta\rho}{(\rho_0 + \Delta\rho)P}$$

and the computations can be made directly from Tables 1 and 2 of the paper.

The initial values of K , computed this way, will be the same as in Figs. 6 and 7 of the paper, but the values at 10,000 psi will be 50 to 70 per cent higher.

The writer has had occasion to reduce the data reported in the paper to analytical expressions of the form $\rho = \rho_0(1 + \Delta P + bP^2 + cP^3)$. The values of the coefficients thus obtained are given in the following table:

Temp. deg F	ρ_0 gram per cu cm	a in. ² /lb	b in. ⁴ /lb ²	c in. ⁶ /lb ³

ALFRED WEISSLER.¹¹ This interesting paper introduces a greatly improved instrument for the determination of isothermal compressibility. The measurement of sound velocity by means of the ultrasonic interferometer is an attractive, precise method for the determination of adiabatic compressibility, from which the isothermal compressibility may be computed if the heat capacity and thermal expansion coefficient are known.¹²

The latter method was utilized¹³ to measure the compressibilities (at atmospheric pressure and 86 F) of 16 methylsiloxane liquids, including the two studied in the present work. It is interesting to note that the values obtained from ultrasonic propagation are about 20 per cent higher than those found in the paper. This difference may be understood in terms of the rapid decrease in compressibility with increasing pressure, as shown in Figs. 6 and 7 of the paper. Inasmuch as the excess pressure attained in our ultrasonic interferometer is 0.1 psi or less, the compressibilities obtained thereby are valid for the range of 0 to 0.1 psi (gage). By contrast, the first measurement at each temperature in the present work gives the "average" compressibility over the range 0 to 100 psi (gage), from which it is not possible to extrapolate to zero pressure with any great accuracy. In the same connection, the isothermal compressibilities of these liquids determined at Dow Corning are considerably lower than those found in the present work, presumably because an even larger pressure interval was used.

It appears, therefore, that the ultrasonic interferometer is particularly valuable for the measurement of compressibility of fluids at zero gage pressure.

AUTHOR'S CLOSURE

The author gratefully acknowledges the stimulating discussion submitted by Professor Bridgman, Dr. Dow, and Messrs. Exline and Weissler, each of whom has made valuable contributions in the field of compressibility.

The corrections for changes in length of the micrometer screw because of temperature and pressure changes and for compression of the material of the vessel, suggested by Dr. Dow and Mr. Exline, respectively, are well within the reported probable error on the density ρ of 0.3 per cent. That the results could be im-

¹³ See reference (8) in Bibliography of paper.

proved by these and other corrections¹⁴ is true, although in many cases it is questionable if the increased accuracy obtained would justify the additional labor in computation.

The instrument described was designed as an engineering instrument with which results sufficiently accurate for most engineering uses could be obtained rapidly by a semiskilled technician with little supervision. The direct readings on the micrometer screw, the facility of testing at various temperatures, the single filling of the bellows for all temperatures and pressures investigated, and the omission of higher-order corrections to simplify the computations, are considered important features in the use of the instrument for engineering purposes.

The maximum possible precision obtainable with the instrument has not been investigated. Professor Bridgman's suggestion of comparison with measurements by other methods, and the application of corrections, such as those suggested by Dr. Dow and Mr. Exline, would be necessary in an investigation to determine the limits of accuracy obtainable with the instrument.

The maximum pressure and temperature to which the instrument could be used are limited primarily by the materials incorporated in the design. Synthetic-rubber O-ring seals in similar applications have been subjected to 40,000 psi at room temperature and to 12,000 psi at 400 F without failure in either case. The maximum temperature, however, is limited to approximately

350 F because a soft solder was used to join the bellows to the bellows plugs.

The isothermal compressibility K , defined by Mr. Exline, is approximately the integrated average between atmospheric and pressure p of the isothermal compressibility k shown in Figs. 6 and 7 of the paper. That Mr. Exline obtained results at 10,000 psi 50 to 70 per cent higher than those presented in Figs. 6 and 7, is therefore to be expected. In the opinion of the author, the isothermal compressibility defined by Equation [5] of the paper is more useful than that defined by Mr. Exline for theoretical analyses leading to calculations of such quantities as adiabatic compressibility and velocity of sound.

Mr. Exline's empirical equation for the density results should be useful, provided the user bears in mind that such expressions cannot safely be extrapolated nor differentiated. Since the labor involved in the evaluation of coefficients is considerable, Mr. Exline's contribution is especially appreciated.

Mr. Weissler's work¹⁵ on the adiabatic compressibility of methyl-siloxane liquids permitted him to calculate the isothermal compressibility at atmospheric pressure. His discussion unquestionably explains part of the difference between his results and those of this paper. Some of the difference, however, probably lies in the uncertainties in the quantities used in his calculations, notably the thermal expansivity and the specific heat at constant pressure.

A Mathematical Evaluation of Pressures in a Grease-Lubricated Bearing¹

By K. B. LAWRENCE,² STATE COLLEGE, PA.

Of the various methods proposed in the past for the numerical evaluation of pressures developed in a film of lubricant, perhaps the best method, in general, consists of the application of a finite-difference formula developed from the fundamental differential equation. Such a formula has been developed by Derman G. Christopherson (1),³ who also has shown that the formula gives accurate results when applied to calculations involving oil-lubricated bearings. The author herein applies the finite-difference formula to calculations of the pressure distribution existing in a grease-lubricated bearing and compares the results obtained with the results of a recent experimental investigation by Cohn and Oren (2), which was conducted under similar conditions of operation.

NOMENCLATURE

The following nomenclature is used in the paper:

- $a = r/L$ = dimensionless radius of a circle constructed about a central node o , which includes the surrounding nodes n upon its circumference
- A_o, A_{o-n} = influence coefficients
- C = eccentricity factor
- E = eccentricity of journal, in.
- F_o, F_{o-n} = residuals
- h = radial clearance or film thickness at point in film, in.
- h_o = radial clearance at point of closest approach
- $H = h/h_o$ = dimensionless ratio of radial clearance to radial clearance at point of closest approach
- L = length of bearing surface in direction of relative motion, in.
- $M = Z/Z_o$ = dimensionless ratio of absolute viscosity at points in film to viscosity at inlet to convergent section of channel
- n = subscript denoting points on circles of radius a or $2a$
- o = subscript denoting centers of circles
- p = pressure $\left[\frac{6Z_o UL}{(h_o)^2} \right] P$, psi
- P = dimensionless pressure
- U = rate of shear of viscous lubricant at point in film, ips
- x = distance measured in direction of relative motion, in.

y = distance measured in the plane of, and at right angles to relative motion, in.

Z = absolute viscosity at point in film, poise

Z_o = absolute viscosity at inlet to convergent section of channel, poise

η = radial clearance, in.

$\xi = x/L$ = dimensionless ratio of lengths measured along bearing arc from inlet position, to total length of bearing arc

INTRODUCTION

A method is to be shown herein for the solution of the pressure distribution in bearings lubricated with a copious supply of a non-Newtonian substance such as a grease or a polymer-laden oil. This subject is of considerable interest at the moment and has presented a problem of some difficulty because of the viscosity characteristics of the lubricants mentioned.

It has been shown by M. H. Arveson (3) and others that the apparent viscosity of greases varies as some function of the rate of shear, indicating an infinite value at zero rate of shear, with the viscosity approaching a constant value at extremely high rates of shear, such as indicated in Fig. 1. This effect is important in any analytical consideration of grease as well as of

FIG. 1 VISCOSITY CURVES

other non-Newtonian substances used as a lubricant, inasmuch as the rate of shear is a variable under the conditions of thick-film lubrication of journal bearings.

It has been shown in hydrodynamic theory that the following equation formulated by Osborne Reynolds (4) applies in conditions of journal-bearing operation utilizing a copious supply of a viscous lubricant

$$\frac{\partial}{\partial x} \left(\frac{h^3}{Z} \frac{\partial p}{\partial x} \right) + \frac{\partial}{\partial y} \left(\frac{h^3}{Z} \frac{\partial p}{\partial y} \right) = 6U \frac{dh}{dx}$$

This equation, although admitting certain simplifications, remains general in so far as the viscosity characteristics of the lubricant are concerned, allowing viscosity changes in both

the X and Y -directions for any cause whatsoever. Considerable difficulty has been experienced, however, in the determination of a general, easily understood, and readily workable method for the solution of this equation. Much important work has been done in this respect by Reissner (5), Vogelpohl (6, 7, 8), Skinner (9), Kingsbury (10), and Christopherson (1). It is the last-named to whom we are indebted for the finite-difference formula which is to be used in this work.

In its very simplest elements, the solution of a differential equation in finite-difference form consists of the substitution of finite quantities in the place of the infinitely small differentials existing in the original. On this basis then, the equation containing the finite differences lends itself to numerical computations—however, at the sacrifice of accuracy. On the other hand, a satisfactory degree of accuracy can be obtained by limiting the finite differences to suitably small intervals simply as one approximates the slope of a graph by considering differences in the ordinates over suitably small intervals.

Christopherson (1) has determined the following finite-difference expressions as solutions of Reynolds equation:

$$\sum_{n=1}^4 a \left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_a \right] P_n - P_o \sum_{n=1}^4 a \left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_a \right] = 2a^2 \frac{\partial H}{\partial \xi}$$

which is accurate to the order of a^2 , or

$$16 \sum_{n=1}^4 a \left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_a \right] P_n - \sum_{n=5}^8 2a \left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_a \right] P_n - P_o \left\{ 16 \sum_{n=1}^4 a \left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_a \right] - \sum_{n=5}^8 2a \left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_a \right] \right\} = 24a^2 \frac{\partial H}{\partial \xi}$$

which is accurate to the order of a^4 .

The summations in the foregoing equation apply to points equally spaced on the circumference (n -points) and at the center (o -points) of circles of radius a or $2a$ such as shown in Fig. 2, situated in the hydrodynamic field in the plane of relative motion. These points are thought of as nodes formed by a grid of equally spaced lines covering the field which is transformed into the X, Y -plane as is shown in Figs. 2 and 3, where the latter shows the fine-grid node construction.

It is necessary also to apply the relaxation method of Southwell (11) to the results determined by the foregoing formulas, since these results will be in error due to the necessity of using a coarse grid, Fig. 2, at the starting points.

VISCOSITY ANALYSIS

Data are given in Table 1 for the reference grease which is to be used in the calculations. These data are for the same grease tested and reported by Cohn and Oren (2).

TABLE 1 CAPILLARY VISCOSITY DATA

FIG. 3 FINE-GRID NODE ARRANGEMENT

A mathematical formula is fitted to each of the viscosity sets of values by a standard textbook method (12) which results in the following

$$Z(\text{at } 77 \text{ deg F}) = 10,960 \left(\frac{U}{h} \right)^{-0.8018} + 6.8$$

$$Z(\text{at } 115 \text{ deg F}) = 6377 \left(\frac{U}{h} \right)^{-0.7800} + 1.82$$

This is done in order to extrapolate the existing data in the direction shown dotted in Fig. 1.

SOLUTION OF FINITE-DIFFERENCE FORMULA

A cylindrical 1-in. \times 1-in. bearing is selected for investigation. The bearing surface is transformed as in Fig. 2, and an area as indicated is selected for investigation in which positive hydrodynamic pressures are anticipated. Furthermore, the area, consisting of 2 in. of the bearing arc, is selected in particular to enable initial calculations to be made for pressures at nodes 6, 10, and 14, involving only pressures at nodes on the boundaries where the values for P_n are known to be zero.

The appropriate physical values are determined in the following calculations:

$$C = \text{eccentricity factor} = 0.46 \text{ (assumed)}$$

$$\eta = \text{radial clearance of bearing and journal} = 0.0082 \text{ in.}$$

$$E = \text{eccentricity of bearing and journal centers}$$

$$= 0.46 \times 0.0082 = 0.00377 \text{ in.}$$

$$\text{Mean film temperature } 115 \text{ F (assumed)}$$

$$\text{Journal speed } 250 \text{ rpm}$$

$$h_0 = \text{minimum film thickness} = 0.0082 - 0.00377 = 0.0044 \text{ in.}$$

$$h_s = \text{film thickness at entrance} = 0.0082 - 0.00377 \cos 20 \text{ deg} = 0.0117 \text{ in.}$$

$$\frac{U}{h_s} = \text{rate of shear at entrance} = \frac{\pi \times 1 \times 250}{60 \times 0.0177} = \frac{13.1}{0.0177}$$

$$= 1119 \text{ reciprocal sec}$$

$$Z_s = 6376 (1119)^{-0.789} + 1.82 = 30.6 \text{ poises}$$

$$\xi = \frac{x}{L} = \frac{r \theta}{L} = \frac{0.5 \theta}{2} = \frac{\theta}{4}$$

$$\begin{aligned}\alpha &= \theta + 20 \text{ deg} \\ H &= \frac{h}{h_s} = \frac{\eta + E \times \cos \alpha}{h_s} = \frac{\eta}{h_s} + \frac{E}{h_s} \cos (4\xi + 20) \\ \frac{\partial H}{\partial \xi} &= \frac{-4E}{h_s} \sin (4\xi + 20) = \frac{-4 \times 0.00377}{0.0044} \sin \alpha \\ &= -3.425 \sin \alpha\end{aligned}$$

TABLE 2

Node	α	%	H	U/h	Z	$M = Z/Z_s$	H^2/M	$\frac{\partial H}{\partial \xi}$
2	20	0.0177	2.66	1119	30.6	1.000	18.90	
6	77°18'	0.0090	2.042	1457	25.4	0.830	10.28	-1.932
10	134°36'	0.0056	1.272	2340	18.2	0.595	3.46	-2.442

It is to be noted in Table 2 that the viscosity of the grease calculated at each of the nodes is based upon the circumferential rate of shear which is assumed to be constant across the thickness of the film. This involves two cases in point. The one case involves the assumption just mentioned, and amounts to the neglect of the second-order effect of pressure on the velocity distribution across the film thickness. Further, it may be reasoned that the rate of shear as a function of x and y should be determined correctly in the direction of the flow at the points under consideration. However, since the flow in the X -(or circumferential) direction is of such a higher order of magnitude than the flow endwise at any point, it is reasoned that the circumferential rate of shear will be a satisfactory approximation and most especially so in this, the case of the highly viscous grease where the end flow is exceedingly low.

The dimensionless pressure at node 6 is now calculated as a sample

$$\begin{aligned}a &= \frac{0.5}{2 \times 0.707} = 0.3535 \\ P_6 &= \frac{2(0.3535)^2 \times 3.345}{2(18.9) + 2(3.46) + 4(10.28)} = 0.00974\end{aligned}$$

The pressures at nodes of progressively finer grids are calculated in a similar manner, using values at nodes previously determined.

Since the formula gives accurate results only for fine grids and the foregoing values were based upon values determined initially for an exceedingly coarse grid, it is necessary now to reduce the error by the relaxation technique.

APPLICATION OF RELAXATION METHOD

Numerical values called residuals are calculated by the reapplication of the finite-difference formula. The residuals defined by

$$\begin{aligned}F_0 &= \sum_{n=1}^4 a \left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_s \right] P_n - \\ &\quad P_0 \sum_{n=1}^4 a \left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_s \right] - 2a^2 \frac{\partial H}{\partial \xi}\end{aligned}$$

are in effect the numerical inequalities existing in the equation due to errors in the pressures. It is seen from the formula that a change in the residual may be made by effecting a change in the P_0 ; in addition, a change in P_0 results in an accompanying change in the residual at the neighboring nodes. To facilitate making these changes the quantities

$$\left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_s \right]$$

and

$$\sum_{n=1}^4 a \left[\left(\frac{H^3}{M} \right)_n + \left(\frac{H^3}{M} \right)_s \right]$$

are given symbols A_{0-n} and A_0 , respectively, and are called influence coefficients. Then at the center

$$\Delta P_0 = - \frac{\Delta F_0}{A_0}$$

and at the n -nodes

$$\Delta F_n = \Delta P_0 \times A_{0-n} = - \Delta F_0 \frac{A_{0-n}}{A_0}$$

The ratios A_{0-n}/A_0 are calculated in advance and serve as multipliers.

In the manner then of reducing the residuals at each of the nodes successively according to the formulas given, values of corrected dimensionless pressures are obtained.

In this, the first case, an additional series of calculations are necessary to extend the area under consideration throughout the convergent section of the channel. The results obtained thereby are given in Table 3 and plotted in Figs. 4, 5, 6, and 7, as the No. 1 set of curves.

In a similar manner the values for the No. 2 set which were taken at the lower temperature, are determined, with the exception, however, that instead of determining initially approximate pressures by means of the formula, a rather arbitrary pressure distribution is assumed and corrections are made thereto by the relaxation method.

The No. 3 set of curves shows the results at the conditions of a higher temperature and increased eccentricity factor. These curves result from the application of the second and more accurate finite-difference formula in the determination of the residuals.

SUMMARY

The reader's attention is invited first to the consideration of the viscosity curves in Fig. 1. It is here noted that the apparent viscosity levels off asymptotically at high values of rate of shear, which phenomenon has been reported by M. H. Arveson (3) and others, based upon experimental evidence. The term apparent viscosity is here used advisedly since the data given were determined by the capillary-tube method, and there is some question as to its applicability because of the possible coring effect in the capillary, which may be attributed to the non-Newtonian characteristic of the grease. However, these data are of sufficient accuracy to demonstrate the general behavior of the lubricant.

The curves in Figs. 4, 5, 6, and 7 are qualitatively similar to those of the oil family; however, no quantitative comparison is attempted here because of the basic differences in the two types of lubricants and the impracticability of establishing the conditions for a rational basis of comparison.

Finally, the curves in Fig. 8 are to be noted. Here the curves for the No. 2 set of conditions are compared with those determined by an experimental investigation by Cohn and Oren (2) on a bearing of similar dimensions. The latter are shown dotted. Rather good conformity is therein noted, although it should be emphasized that there is considerable uncertainty concerning the comparableness of some of the corresponding physical conditions existing in the two cases. Possibly the most notable deviation is the diversity in the unit radial clearance. In this work the value of 0.0164 in. per in. was used, while Cohn and Oren report for their bearing a value of 0.0071 in. per in. Of similar importance

is the matter of the running position of the shaft, since there is no reported value of eccentricity in the experimental investigation. The constant mean film temperature, as assumed herein for the lower (77 deg F) cases, roughly approximates the bearing shell temperatures observed by Cohn and Oren, and, although the finite-difference formula is adaptable to temperature variations in the film, no allowance was made for this occurrence in this work.

It is also to be noted that although the curves were plotted to the same scale on the abscissa, their relative location was chosen arbitrarily, since this mathematical treatment does not determine directly the angular position of the application of the load.

CONCLUSIONS

This work is presented as an illustration of the use of the finite-difference formula as applied to determining the pressure distribution in a journal bearing using grease as a lubricant. In a similar manner, this same method can be used equally as well where other non-Newtonian substances are used, as well as Newtonian substances. This method may be considered as valid in so far as the assumptions made herein apply, and presents the possibility of the establishment of a simpler method which can be applied to everyday lubrication problems involving non-Newtonian lubricants. This can be accomplished through the analytical survey of the whole field of application by this method. Then the evolution of a semianalytical method can be brought about, constructed on a rational basis.

Investigation of Lubricants for Power Circuit Breakers

By R. R. BUSH,¹ PHILADELPHIA, PA.

This paper describes a technique for the selection of proper lubricants for power circuit breakers. The circuit breaker is described briefly, and its lubrication requirements for dependable operation are discussed. The laboratory methods set up to determine the performance of the grease best suited for this application are outlined. Results of the laboratory test data are shown and evaluated with reference to circuit-breaker requirements. Properties of some typical greases are compared with their performance for this particular application. Because performance depends not only upon grease properties, but also upon the process of manufacture, the greases tested are referred to only in code. Life tests on actual circuit breakers have checked laboratory results. Therefore it is concluded that tests may be set up to determine the suitability of a lubricant for any particular application and especially for power circuit breakers.

INTRODUCTION

PROPER lubrication of power circuit breakers is a problem of considerable importance because the operation of the entire power system depends so completely on the reliable operation of the breakers under any emergency. When a short circuit occurs on a power line, the portion in which the disturbance originated must be isolated quickly to prevent damage to associated apparatus and to restore service to the rest of the system. Its entire operation must be completed in less than $\frac{1}{10}$ sec. To obtain this high-speed operation, friction of all moving parts must be held to a minimum. The better the lubrication of all friction points, the lower the friction which will be encountered. This means higher speed of operation and longer life of all moving parts.

The lubrication problem in power-circuit-breaker bearings and other friction points is peculiar in that the motion is extremely intermittent, generally oscillatory, and generally heavily loaded. The contacts of the power circuit breaker are opened in response to the operation of a high-speed relay by means of a powerful driving force properly connected through cranks, cams, and rollers. The driving force is generally obtained from energy stored in compressed springs, or compressed air. Quick opening is accomplished by suddenly releasing this stored energy. Each passing year has seen the size and speed of circuit breakers increase. With each such increase, the duty on bearings has also increased, as indicated in Fig. 1. To keep friction and maintenance to a minimum, better and better lubricants have been required. Hand in hand with this development went the choice of the proper lubricant for the bearings depending on the duty they perform.

FIG. 3 LOW-OIL-CONTENT IMPULSE-TYPE OIL CIRCUIT BREAKER
RATED 10,000,000 KVA AT 360,000 VOLTS
(Interrupting time 0.05 sec.; reclosing time 0.167 sec.* Inset of breaker from
Fig. 2 compares sizes.)

Its 6 sets of contacts are designed to carry 1000 amp continuously, to open in 0.05 sec and reclose in 0.16 sec. For comparison of size, the inset at the lower left-hand corner shows the breaker from Fig. 2 to the same scale as this breaker. The development of most modern breakers would not have been possible without corresponding development in bearings and lubricants to keep friction to a minimum.

LUBRICATION REQUIREMENTS OF MODERN BREAKERS

It is well known that greases provide better lubrication than oils for power circuit breakers because they stay in the bearings better than oils under high pressures. They also exclude dirt to a greater degree than oils. This is especially true on textolite bearings,² and open antifriction or rolling-friction bearings. However, grease lubricants tend to stiffen up with time because of oxidation. In bearings in circuit-breaker mechanisms, where the available torque for initiating operation is low, this added friction may be serious because it may prevent the circuit breaker from opening. Some breaker bearings have been found in service in which the grease was practically solid around the rollers of trip latches. In cases when such breakers opened, it was found that the opening time had increased 3 to 5 times. This may be very serious under short-circuit conditions. Further investigation of

these cases showed the torque required to operate the trip latch had increased several times over the normal torque required for tripping, because of hardened grease. The only assurance users have had of proper operation of circuit breakers has been periodic checking with a time-travel recorder to see that they have the proper speed. On outdoor breakers, located in cold climates, the increase in consistency, or decrease in penetration, with temperature is also a problem with many greases.

Another duty that greases must perform in power circuit breakers is protection from corrosion and rusting of bearings and other sliding metal parts, both during storage before placing in service, and after being placed in service. Humidity or corrosive atmospheres are particularly severe on roller bearings unless they are properly protected with a film of lubricant.

In sleeve bearings, the coefficient of friction varies widely with the type and condition of the lubricant. This is critical because of the high bearing pressures used in circuit breakers. With older metallic-bushing bearings, the grease film must persist at pressures around 7000 psi and in the modern textolite-bushing bearings at around 10,000 psi. Many greases may be found to satisfy one or more of the requirements just outlined, but to find one which will satisfy all these requirements is much more difficult.

The dependable and trouble-free operation of power circuit breakers under all conditions, however, dictates that the lubricant used meet all these requirements. Preferably a single lubricant should be used in all locations of a given circuit breaker to avoid the necessity of selection on the part of the maintenance crew and to avoid the stocking of several types of greases. Hence this investigation was initiated to determine the best type of lubricant for use in modern power circuit breakers. It must be realized that the best grease from an over-all standpoint will not necessarily be the best grease from all standpoints. This review, therefore, is presented more to point out the method of investigation rather than as a grease recommendation; and, accordingly, all greases are referred to by number only.

METHOD OF ATTACKING THE PROBLEM

Engineers from a number of lubricating companies were asked to review the problem. All agreed it was worth while to look for one grease, although the possibilities of finding one suitable for all operating conditions were doubtful. Accordingly, the following specifications were set down for the grease:

- 1 High resistance to oxidation.
- 2 Operating temperature range from -30°F to $+150^{\circ}\text{F}$.
- 3 Good lubricating qualities.
- 4 Good corrosion protection.
- 5 Must not be forced out of bearing under high pressure.

With these points in mind, some thirty different greases were recommended for investigation.

The first check was on oxidation. The shelf life of the grease was considered the criterion for grease in antifriction bearings, because of the short working life and intermittent oscillatory motion imposed on them in circuit breakers. The Norma-Hoffman bomb test gave the best laboratory measure of this property, but the test was time-consuming.

For textolite sleeve bearings, it was considered that the oxidation of a thin film would be more indicative of the lasting qualities of the grease. In order to produce thin films for oxidation tests, a tool, shown in Fig. 4, was devised, the knife-edge of which spread an even thin film of grease on a chromium-plated steel plate measuring 1 in. \times 5 in. \times 12 in. This plate was lapped to a flatness of about 15 microinches before flash-plating with chromium about 0.0002 in. thick. The 0.001-in. thickness of

FIG. 4 APPARATUS FOR THIN-FILM OXIDATION TESTS

FIG. 5 BEARING TEST MACHINE FOR LIFE TEST AND FRICTION MEASUREMENTS

the film of grease as laid down was checked to within 0.0001 in. by a Gardner interchemical thickness gage.

Several greases were put on the plate at the same time and then placed in a circulating oven at 100 C. It was considered that any grease used for this purpose should remain relatively intact at this temperature and that the oxidation would be accelerated to give a comparative answer in a reasonable time. Greases which were not acceptable lost their lubricating properties in as short a time as 24 hr while many of the more acceptable ones lasted at least 120 hr. Some of the best greases retained their lubricating properties for even longer periods.

As soon as a grease indicated it might pass the thin-film oxidation test, it was checked in an ordinary refrigerator for 48 hr to see if it showed stiffening as lowered temperatures occurred. If it indicated satisfactory performance under these conditions, the grease was put on friction test in textolite bearings on the test machine shown in Fig. 5. Corrosion tests also were run at this time in both salt-spray and humidity chambers.

The friction test was run 100 operations at 8000 psi of projected area, 100 operations at 10,000 psi of projected area, and 100 at 12,000 psi. Starting and running friction were measured after each of the steps and if everything appeared satisfactory, a 14,000 operation life test was run at 12,000 psi. Starting and moving friction were determined at intervals during the run. Also, the machine was left standing overnight and over week ends and the starting friction measured just before resuming the run. The frictional values for both starting and running were compared because both are equally important in circuit breakers which must trip instantly and open at high speed. When a grease had passed the friction test, the thin-film test, the refrigerator cold test, and appeared to be satisfactory on the corrosion tests, then a Norma-Hoffman oxygen-bomb² test, and a torque-temperature

² "Some Applications of an Accelerated Test for Determining the Chemical Stability of Lubricating Greases," by F. L. Wright and H. A. Mills, Proceedings of the ASTM, vol. 38, part 2, 1938, pp. 525-538.

test in a ball bearing were run. To check with types of sliding bearings other than textolite, friction runs were also taken on bronze bearings. Evaporation tests were also made on those greases which showed promise.

With the laboratory tests all satisfactory, the grease was then put in actual circuit breakers as a final check.

RESULTS OF TESTS

Following will be a review of the results of tests made on a representative number of the greases investigated. It must be realized that any statement given applies only to the peculiar application investigated under the conditions outlined and is not a criterion for that grease under conditions different from those under consideration. Also, for the purpose of avoiding any possible undesirable reflection on any product, the greases are coded with only number reference. Table 1 is a tabulation of general performance as determined by test. Since readings were comparative, designations are listed as "acceptable" or "unacceptable." If any grease approaches acceptable in any given requirement, it is marked unacceptable and starred to indicate that further investigation is warranted. Table 2 lists general properties of several representative types of these greases together with general performance. Space does not permit listing all greases tested. Again, it is realized that the properties do not tell the whole story as to how a grease may perform. They are given merely to show any relation they might have to their performances under the conditions tested.⁴ For better understanding of these tables, the following curves show typical detailed test data.

Fig. 6 shows the performance of two greases acceptable for friction. Fig. 7 shows the performance of two greases unacceptable for bearing friction. No grease was considered acceptable which showed a marked tendency to exceed 0.10 coefficient of starting friction during a run. Starting friction after a long period of rest might exceed this figure but would not be desirable. The maximum reached when grease 21 was used was 0.128 in one case. With grease 14, the coefficient of friction never exceeded 0.11 when the grease was new. However, when quite old, it would permit scoring of the bearings and pin after a short run at the high pressures involved. Fig. 8 illustrates oxygen-pressure loss with time in the Norma-Hoffman bomb. These curves give relative resistance to oxidation of four different greases.

Fig. 9 shows torque-temperature properties of two greases of widely different composition. Both of the greases illustrated were acceptable on this test as it indicates low torque on ball bearings in cold weather. Fig. 10 illustrates the loss by evaporation of 5-g samples of different greases placed in an oven at 210 F.

Examination of the tables and charts will reveal that grease 21, when compared with others, performed most consistently acceptable in all tests to which it was submitted. It also will be noted that while its average performance is good all around for the purpose investigated, other greases exceeded it on some points; but fell down on others.

It appears that inhibitors against oxidation are mandatory. Rust inhibitors are a help against corrosion, but other ingredients may accomplish this protection. The sodium soap base appears to perform better on resistance to oxidation than calcium soap base, but either is good on friction when formulated with petroleum oil having in the neighborhood of 275 SUS viscosity at 100 F, and showing a consistency of around 275 penetration. The lithium soap base with a 300 SUS viscosity performed much better on the friction machine than those with lighter oils,

although the test results did not show up good enough. Generally, they gave the least protection in corrosion tests but showed very good resistance to oxidation.

It may be of interest here to mention that dry lubrication was tried on textolite bearings and stainless-steel shafts without success at any pressures in the ranges considered.

After the laboratory tests, grease 21 was put on life tests on large and small-sized breakers. Its performance met expectations in all cases except on high-speed open gearing. It lacked the ability to stick fast on these fast-rotating parts. Circuit breakers have few such applications in their design.

CONCLUSIONS

Review of the data reveals that much investigation is necessary to determine the suitability of a lubricant for any particular apparatus. It was possible to find a grease that fulfilled most of the

requirements set down for the particular application. For a few very special considerations a special lubricant is necessary. Investigation shows that laboratory tests are the quickest and the most reliable way to check a large number of possible greases for a specific application. Results obtained in an actual circuit breaker gave performance far superior to any of the standard greases previously used for this application. Each application,

however, will require its own peculiar tests of several lubricants, and different weights will be given to each characteristic to arrive at an acceptable solution for that application. Life tests then must be made on the apparatus itself to insure that performance on all points is satisfactory. In circuit breakers, such a lubrication investigation has yielded results far better than could have been obtained in any other way.

Discussion

V. L. BARR.¹ One very important point which needs restressing is that this work was conducted to find a suitable lubricant for sleeve-type bearings, primarily textolite. The bearing pressures shown in Fig. 1 of the paper, for instance, are for this type bearing and not antifriction bearings. Successful applications of needle-type bearings under similar service conditions operate at much higher loading on a projected-area basis.

The data presented are applicable to antifriction bearings, but not in the same order of importance as shown in this paper. For ball and roller bearings, we would list the requirements in the following order:

¹ Director of Engineering, Roller Bearing Company of America, Trenton, N. J. Jun. ASME.

- 1 Resistance to oxidation.
- 2 Wide temperature range of operation.
- 3 Corrosion protection.
- 4 Good lubricating qualities.

The author's last requirement has no particular interest for antifriction bearings.

For the particular service required in circuit breakers, we are not too concerned with the lubrication properties of a grease. For continuous-rotating applications, however, this is not true.

With these points in mind and reviewing Table 1 of the paper, it is the writer's opinion that grease No. 16 would be very satisfactory for the antifriction bearings used in circuit breakers. Assuming corrosion conditions are not too severe, grease No. 2 would be highly satisfactory. Grease No. 11 we feel should be investigated further since it may be satisfactory for antifriction bearings.

Perhaps from Table 2 some of the greases may be recognized in terms of governmental specifications. In this respect, it is our opinion that service received from various manufacturers' products, meeting a particular specification, is quite varied. We believe any specifications for lubricants should include more performance-test requirements.

To stress further the difference in requirements between sleeve bearings and antifriction bearings, the variation between greases Nos. 21 and 16 from Fig. 9 will be noted. Grease No. 16 is much more desirable at the extreme low temperatures, yet, on the friction machine, grease No. 16 is unsatisfactory, while No. 21 was acceptable.

This last point suggests that for sensitive tripping mechanisms in extreme cold it may be absolutely necessary to use a grease such as No. 16 in the antifriction bearings.

AUTHOR'S CLOSURE

Mr. Barr has ably pointed out the difference between the requirements of an antifriction bearing used in a power circuit breaker and those of the same bearing working under what might be termed the usual running conditions. It must be remembered, however, that the grease selected for this application operates successfully in both the antifriction bearings and the textolite sleeve bearings working under the intermittent oscillatory motion encountered in circuit breakers.

Had the problem been restricted entirely to antifriction bearings, both greases No. 16 and No. 2 would have given better operation at lower temperatures than was required. Grease No. 11, however, was not as good in this respect as grease No. 21 which was chosen. The need for one all-purpose grease was imperative for this application and the selection was made on this basis.

The suggestion that specifications for lubricants should include more performance-test requirements is very timely. These requirements should be such that they can be checked in the laboratory with reasonable facility. The time required to work out a suitable set of tests as a procedure for screening the lubricants before final life tests will yield dividends. Each application will require its own peculiar tests of several lubricants, and different weights will be given to each characteristic to arrive at an acceptable solution for the application being considered.

Heat Transfer to Superheated Steam at High Pressures

By W. H. McADAMS,¹ W. E. KENNEL,² AND J. N. ADDOMS³

Local coefficients of heat transfer from a 12.3-in. length of 0.252-in. tubing to steam flowing upward in a vertical annulus were measured for pressures from 115 to 3500 psia, for temperatures from 430 to 1000 F, and for temperature differences from 100 to 620 F. All results are correlated in Fig. 8 in terms of the local Nusselt number, the Reynolds number, the Prandtl number, and the geometrical ratio L/D_s , with the physical properties evaluated at the film temperature. An improved correlation, employing new data on thermal conductivity, is presented in Fig. 10 of the Addendum.

NOMENCLATURE

The following nomenclature is used in the paper:

- A = area of heat-transfer surface, sq ft
- a = constant, dimensionless
- c = specific heat of fluid at constant pressure, Btu/(lb) (deg F)
- D = diameter, ft
- D_s = equivalent diameter, equal to 4 times the hydraulic radius based on total wetted perimeter, ft
- d = prefix, indicating first derivative, dimensionless
- f_m = mean value of friction factor, dimensionless
- G = mass velocity of fluid, lb/(hr) (sq ft of cross section)
- h = local coefficient of heat transfer, Btu/(hr) (sq ft) (deg F); h_m for mean value
- I^2R = rate of electrical generation of heat in wall of heater, Btu/hr
- K = function of L/D_s , defined by Equation [9]
- k = thermal conductivity of fluid, Btu/(hr) (ft) (deg F); k_A for wall of heater
- L = length of heat-transfer surface, ft
- m = exponent, dimensionless
- q = rate of heat transfer, Btu/hr
- q/A = density of heat flux, Btu/(hr) (sq ft)
- r = radius of wall of heater, ft
- S = cross section for fluid flow, sq ft; $\pi D^2/4$ inside tubes; $\pi(D_2^2 - D_1^2)/4$ in annuli
- t = bulk temperature of fluid, deg F
- V = average velocity of fluid, based on density at bulk-stream temperature, ft/hr
- X, X', X'' = abscissas of Figs. 4, 5, 6, dimensionless
- x_A = thickness of wall of heater
- Y, Y', Y'' = ordinates of Figs. 4, 5, 6, 8
- Δt = temperature potential, deg F

INTRODUCTION

The object of this investigation was to determine local or point coefficients of heat transfer from metal to superheated steam at pressures up to 3500 psia, for a heater having an outside diameter of 0.25 in., concentrically located in an unheated vertical jacket having an inside diameter of 0.382 in. Mass velocities in the annulus were to be restricted to the range from 55,000 to 165,000 lb per hr per sq ft of cross section. Heater temperatures were to be as high as possible.

REVIEW OF THE LITERATURE ON HEATING AND COOLING

Turbulent Flow Inside Tubes. Various mathematical analogies between the transfer of heat and momentum lead to quantitative relations among four dimensionless moduli as follows:

$h_m D/k$, mean Nusselt number, based on heated length
 $c\mu/k$, Prandtl number, which is ratio of molecular diffusivity of momentum (μ/ρ) to molecular diffusivity of heat ($k/\rho c$)

$$\frac{DV}{\mu/\rho} = \frac{DG}{\mu}, \text{ "diameter" Reynolds}$$

number, which is a ratio of acceleration forces to viscous forces.

f_m , mean friction factor, equal to shear stress at wall, divided by $\rho V^2/2g_c$.

In deriving the analogies, various simplifying assumptions are made, such as, the flow is fully developed and incompressible, the physical properties are independent of temperature, and

the velocity distribution is known and is independent of Δt .

Owing to lack of fundamental information on temperature and velocity profiles, experimental data on mean heat-transfer coefficients are usually correlated empirically in terms of the first three of the dimensionless numbers just listed, or their equivalent. The empirical equations differ as to the temperatures at which the physical properties are evaluated. To allow for variation in properties with temperature, ratios such as μ/μ_w , ρ/ρ_w , and k/k_w are sometimes introduced.

In the last 16 years three types of equations have been accepted generally for predicting coefficients for heating fluids flowing inside tubes:

All physical properties are based on bulk-stream temperature t

$$\frac{h_m D/k}{(c\mu/k)^m} = a \left(\frac{DG}{\mu} \right)^{0.8} \quad [1]$$

Reference: ⁴	a	m	Equation
(6), (12)	0.024	0.4	[1a]
(10), (11)	0.023	0.4	[1b]
(7)	0.021	1/3	[1c]

All physical properties are based on bulk-stream temperature, except μ_f is taken at $t_f = (t + t_w)/2$

Reference:	a	m
(4)	0.023	1/3

All physical properties are based on bulk-stream temperature, except μ_w

$$\frac{(h_m D/k) \left(\frac{\mu_w}{\mu} \right)^{0.14}}{(c\mu/k)^m} = a \left(\frac{DG}{\mu} \right)^{0.8} \quad [3]$$

Reference:	a	m	Equation
(13)	0.027	1/3	[3a]
(2)	0.023	1/3	[3b]

The foregoing equations are based on experimental data for relatively small values of Δt ; at moderate Δt , they predict approximately the same values of h_m for water.

A recent paper (8) reports data on heating air at Δt up to 940 F and at DG/μ from 10,000 to 230,000. Regardless of whether the physical properties were evaluated at the bulk-stream temperature or at the wall temperature, the data fell on curves of changing slope, and the data were lower than predicted by Equations [1a] and [1b]. The data were brought into close agreement (8) by the equation

$$\frac{h_m D/h_w}{(c\mu/k)_w^{0.4}} = a \left(\frac{DV \rho_w}{\mu_w} \right)^{0.8} \quad [4]$$

wherein all physical properties are evaluated at the wall temperature, and a modified Reynolds number

$$\frac{DV \rho_w}{\mu_w} = \left(\frac{DV \rho}{\mu} \right) \left(\frac{\mu}{\rho} \right) \left(\frac{\rho_w}{\mu_w} \right) \quad [4a]$$

was employed. With a bellmouth entry (8), and for L/D of 60, the constant a was 0.022

$$\frac{h_m D/k_w}{(c\mu/k)_w^{0.4}} = 0.022 \left(\frac{DV \rho_w}{\mu_w} \right)^{0.8} \quad [4b]$$

Alternatively, $(c\mu/k)_w$ could be omitted (8) giving

$$\frac{h_m D}{k_w} = 0.018 \left(\frac{DV \rho_w}{\mu_w} \right)^{0.8} \quad [4c]$$

No other data at high Δt are available for heating gases. The

⁴ Numbers in parentheses refer to the Bibliography at the end of the paper.

literature contains no reliable data on heat transfer to steam under conditions of high pressure and high Δt .

Reference (1) shows curves of the local coefficient for air versus L/D for the entrance section of a tube at values of DG/μ from 17,000 to 56,000, for a number of entrance conditions. For flow in a tube following a sudden contraction, the initial value of h (for the first 0.56 diam) was roughly twice that at L/D of 10. Reference (3) reports results for DG/μ from 18,000 to 8000, which indicate that the local heat-transfer coefficient varies as the minus 0.15 power of L/D , for the first 31.5 diam.

Turbulent Flow in Annuli. While several equations have been proposed, the latest is that of reference (2)

$$\frac{h D_e/k}{(c\mu/k)^{1/3}} \left(\frac{\mu_w}{\mu} \right)^{0.14} = 0.023 \left(\frac{D_e G}{\mu} \right)^{0.8} \quad [5]$$

wherein all physical properties, except μ_w , are evaluated at the bulk-stream temperature; D_e is equal to 4 times the hydraulic radius based on total wetted perimeter, and is equal to $D_2 - D_1$.

Further support of the use of D_e is given by the results of reference (5) for rectangular passages; as shown in reference (11),⁴ these data ran 10 to 25 per cent below Equation [1b].

EXPERIMENTAL

Introduction. To accomplish the objectives, an apparatus capable of withstanding pressures of 3500 psia at 1000 F and per-

⁴ Reference (11), p. 198.

FIG. 1 HIGH-PRESSURE APPARATUS, WITH STEEL SAFETY BOOTH REMOVED

(Right foreground, adjustable-stroke 4-cylinder pump, feed reservoir, and condensate-measuring tube. Heavily insulated 13-pass electrically heated series boiler is located in front of the a-c switchboard, and condenser and cooler are visible. Heavily insulated test section, and the d-c busbars, are mounted just behind control panel near nitrogen cylinder.)

FIG. 2 TEST SECTION BEFORE INSULATING

(Leads to thermocouples installed inside heating tube are brought out through nitrogen-pressurized fitting at top. The d-c power connections and potential taps can be seen. Further details shown in Fig. 3.)

mitting accurate measurement of the local heat flow and local temperature driving force was required. Condensing mercury vapor, molten metals, and fused salts were considered as sources of heat but were discarded in favor of electric heat generated in the wall of a metal tube. Because the wall of the electrically heated tube had to be thin to avoid use of excessive current and to minimize longitudinal conduction of heat, it was impossible to use the tube itself as the pressure vessel. Consequently, the electrically heated tube was pressurized internally with nitrogen, and was located concentrically in a high-pressure jacket, thus forming an annular passage for flow of steam.

The procedure was to heat superheated steam as it flowed upward at a measured rate through the annular space. The heat dissipated by the heating element was calculated from electrical measurements; the corresponding temperature of the heating element was determined by measuring the inside temperature and correcting for the radial temperature gradient in the wall. The temperature of the steam was measured at the entrance and exit of the test section and was corrected for heat losses. The point coefficient of heat transfer could be calculated from the data for given flow conditions.

Apparatus. The apparatus was a flow system in which water was drawn from a reservoir and pumped through a preheater, a test section, throttle valves, a condenser and condensate cooler, and back to the reservoir. Views of the apparatus are shown in Figs. 1 and 2. Stainless steel, which has good corrosion resist-

FIG. 3 DETAILED DRAWING OF TEST SECTION

ance and strength at high temperatures, was used as the material of construction. Safety devices included a movable steel booth enclosing the entire apparatus, two rupture disks calibrated to blow at 4400 psia, and an automatic device to shut off electrical power whenever the pressure decreased substantially.

A four-cylinder pump of the positive-displacement type drew water from the reservoir at atmospheric pressure and injected it into the high-pressure system. The flow rate was measured volumetrically at the inlet of the pump.

The preheater, seen in Fig. 1, took cold water from the pump and produced superheated steam at any desired temperature up to 900 F at flow rates up to 75 lb per hr. It consisted of 80 ft of $\frac{5}{8}$ -in. extra-heavy stainless-steel pipe covered with insulation and electrical windings capable of dissipating 35 kw at 110 alternating current. Power to the preheater was controlled by switches on each of 12 electrical windings and by a Variac on the last winding. Total preheater power was indicated by a wattmeter. A spiral strip of stainless steel was inserted in the last two 6-ft lengths of the preheater to impart a centrifugal motion to the fluid, so that any entrained liquid would contact the heated wall and thus be vaporized.

The test section (Figs. 2 and 3), consisted of a vertical annulus in which a stainless-steel heating element was mounted coaxially inside a pressure jacket which had an inside diameter of 0.382-in. Removable end closures on the pressure jacket were equipped with insulated nickel leads which supplied electrical power. The heating element was a stainless-steel tube having an outside diameter of 0.252 in., a length of 12.28 in., and a wall thickness of

0.0332 in. At the lower end it was silver-soldered to an adapter on a flexible connection which served as an expansion joint and electrical lead. At the upper end, the element was silver-soldered to a hollow nickel electrical lead through which were inserted four chromel-alumel thermocouples, spaced at 3-in. intervals. By means of a special fitting on the open end of the upper nickel lead, nitrogen pressure was applied to the inside of the heating element to prevent collapse under the external pressure of the steam.

Iron-constantan thermocouples were installed in wells at the entrance and exit of the test section to measure steam temperatures. Ten thermocouples were installed in small radial holes in the wall of the pressure jacket to permit estimates of temperature at the inner surface.

Power to the test section was supplied by a 15-volt 1000-amp direct-current generator. To measure voltage drop across the heating element a voltage-divider circuit, consisting of a 10-ohm resistor and a 1000-ohm resistor, was connected across the heating element. A calibrated 0.00005-ohm resistor was connected in series with the heating element to determine the current. The voltage drop across the 10-ohm resistor and the 0.00005-ohm resistor, and the potential generated by the thermocouples, were measured by means of a portable precision potentiometer.

Following the test section, $1/8$ -in. and $1/4$ -in. needle valves were installed in parallel to throttle the steam from operating pressure to that at the entrance to the condenser and cooler.

Operating Procedure. Before mounting a heating element in the test section, the resistances of its component parts were determined. The thermocouple assembly was then inserted in the heating element, which was mounted in the test section. The end closures were secured, and the system was pressure-tested.

The throttle valves were opened, the pump was started, and the desired flow rate was set by adjusting the stroke of the pump. The power to the preheater was then turned on and adjusted to approximately the desired value, and the temperature of the system was allowed to rise. The desired operating conditions were approached by adjusting the throttle valves and the power to the preheater. After a final adjustment of the pump to the desired flow rate, the system was allowed to come to a steady-state condition.

The approach to steady-state condition was determined by plotting the difference between the millivolt readings of the thermocouples measuring inlet and outlet steam temperature versus time. When this temperature rise became substantially constant, a run was begun. Each run was made with constant flow rate, pressure, and temperature of the inlet steam.

The first one or two data points in each run were taken with no power to the heating element, in order to determine the heat loss. Data points were then taken at various settings of power input to the test section. Most of the runs were concluded at power inputs such that the temperature inside the heating element did not exceed 1300 F, because early runs showed that operation at higher temperatures caused warping and discoloration.

Method of Calculation. For each setting of power to the test section, the total density of heat flux, the heat transferred by radiation (see Appendix), the temperature of the outside wall of the heating element, the bulk temperature of the steam, the Δt , and the local coefficient of heat transfer were calculated. Each of these factors was evaluated at four positions corresponding to the locations of the thermocouples inside the heating element.

The power dissipated by the heating element was calculated by using the product I^2R where I is the current through the heating element and R is the resistance at the average wall temperature. The density of heat flux was then calculated from the power dissipated and the dimensions of the heating element. The temperature of the outer wall of the heating element was

determined from the temperature of the inside wall by subtracting the temperature drop through the wall

$$t_{wi} - t_{wo} = \left(\frac{dq_i}{dA_o} \right) \frac{r_o}{k_h} \left(\frac{1}{2} - \frac{r_i^2}{r_o^2 - r_i^2} \ln \frac{r_o}{r_i} \right) \dots [6]$$

$$(\Delta t)_w = \left(\frac{dq_i}{dA_o} \right) \frac{x_h}{k_h} \left(\frac{1}{2} + \frac{x_h}{6 D_o} \right) \dots [6a]$$

Equation [6] was derived by assuming uniform generation of heat per unit volume of the wall and constant thermal conductivity at the average wall temperature; Equation [6a] follows upon expansion of the logarithmic term. For the densities of heat flux employed, the $(\Delta t)_w$ calculated from Equation [6a] was sufficiently close to that calculated by allowing for variation of thermal conductivity and electrical resistivity with temperature.

Since the temperature of the steam was measured only at the entrance and exit of the last section, it was necessary to calculate the temperature of the steam at the positions corresponding to the four thermocouples. The heat lost by the steam while it flowed from the entrance to any point in the test section was determined from data at zero heat input. The heat generated by the heating element up to the same position was calculated. The increase in the temperature of the steam from the entrance to the desired location was calculated by difference.

The local rate of heat transfer by the combined mechanisms of conduction and convection (dq_o/dA_o) was obtained by deducting an estimate for radiation (dq_r/dA_o) from the total local flux (dq_i/dA_o). Since the emissivity and absorptivity of water vapor for radiation have not been investigated at high pressure, it was necessary to extrapolate the values from atmospheric pressure (see Appendix). The radiation correction never exceeded 12 per cent and usually was less than 10 per cent.

The local Δt and the local density of heat flux dq_o/dA_o were used to calculate the local coefficient of heat transfer

$$h = \frac{\frac{dq_i}{dA_o} - \frac{dq_r}{dA_o}}{t_{wi} - t} = \frac{dq_o}{dA_o \Delta t} \dots [7]$$

RESULTS

Twenty-seven runs were made, of which twenty-five were successful. The ranges of pressure, temperature, and mass velocity are given in Table 1. Over-all heat balances were good, allowing for heat losses. Points of two kinds were eliminated; those for outer wall temperatures above 1300 F, and those with Δt less than 100 F. The points in the former category were discarded because there was the probability of distortion and oxidation of the heater. All data with Δt of less than 100 F were eliminated, since slight changes in line voltage to the preheater made precise control of the steam temperature difficult; a change of 1 per cent in the preheater power resulted in 10 to 12 F change in steam temperature.

The local Nusselt numbers, Prandtl numbers, Reynolds numbers, length-diameter ratios, and viscosity ratios were tabulated for all the data to be correlated. Local Nusselt numbers at L/D_o of 57 are plotted in Figs. 4, 5, and 6.

Plots similar to Figs. 4, 5, and 6 were made for local Nusselt numbers at L/D_o of 11.4; the trends were similar to those shown in Figs. 4, 5, and 6. In addition, plots similar to Figs. 4 and 6 were constructed for the local Nusselt numbers at L/D_o of 37 and 80.

The effect of L/D_o was determined from Fig. 6 and similar plots. The best straight line was drawn through each set of points, and the constant K in the equation

$$Y^* = K (X^*)^{0.89} \dots [8]$$

FIG. 4 CORRELATION OF DATA AT L/D_s OF 57 (Using co-ordinates of references 2 and 13.)

FIG. 5 DATA OF FIG. 4 REPLOTED WITH CO-ORDINATES OF REFERENCE (8)

FIG. 6 DATA OF FIG. 4 REPLOTED WITH ALL PROPERTIES EVALUATED AT FILM TEMPERATURE: $t_f = (t_w + t)/2$ FIG. 7 CROSS-PLOT OF RESULTS FROM FIG. 6, AND SIMILAR GRAPHS FOR VARIOUS VALUES OF L/D_s

was evaluated for each L/D_s . Fig. 7 shows these values of K plotted against L/D_s , yielding

$$K = 0.0126 (L/D_s)^{-0.13} \quad [9]$$

The final correlation, involving local coefficients at four different values of L/D_s , is given in Fig. 8

$$\frac{(h D_s / k_f) \left(\frac{L}{D_s} \right)^{0.13}}{(c \mu / k_f)^{1/4}} = 0.0126 \left(\frac{D G}{\mu_f} \right)^{0.89} \quad [10]$$

Since the simplified dimensional equation

$$\frac{h}{c G} = \frac{S}{A} \frac{(t_2 - t_1)}{(t_w - t)} = \frac{0.0144}{(D G)^{0.2}} \quad [11]$$

correlates data for certain common gases at moderate Δt , this type of correlation was tried for the present data on steam at one L/D_s . A plot of h/c versus G gave a slope of 0.87, but the maximum deviation from the main line was ± 40 per cent. The term $h/c G^{0.87}$ was plotted versus film temperature, but separate curves were obtained for the several pressures.

FIG. 8. RECOMMENDED CORRELATION OF ALL RESULTS

DISCUSSION OF RESULTS

In Fig. 4 all of the local Nusselt numbers lie below the dotted line of reference (13) for mean Nusselt numbers, and most of the data fall below the dotted line of reference (2). The solid line represents an average of the data. The points at pressures of 3000 to 3500 psia are close to the line, most of those for 115 to 500 psia are above, and most of those for 1000 to 2000 psia are below.

In Fig. 5 the correlation is better than in Fig. 4. The slope of the curve is the conventional value of 0.8, the same as that reported (8) for air flowing in a tube, with Δt up to 940 F. The ordinate contains an exponent of $1/3$ on the Prandtl number, in place of 0.4. For the pressures and temperatures involved, the ordinate would be changed but little by using $(c\mu/k)^{0.4}$ instead of $(c\mu/k)^{1/3}$. Consequently, it is interesting to note that Fig.

5 gives a constant of 0.0226 for the local Nusselt number at L/D_e of 57, as compared with 0.022 for the mean Nusselt number for L/D_e of 60, Equation [4b]. At a given pressure, the thermal conductivity of steam may either decrease or increase with increase in temperature, while for low-pressure air, k always increases with increase in temperature. Furthermore, as temperature increases, the Prandtl number decreases more rapidly for steam than for low-pressure air.

The plot (not shown) of Y' versus X' , at L/D_e of 11.4, gives a constant of 0.0267, which is higher than the constant of 0.0226 at L/D_e of 57.

In Fig. 6 the correlation is distinctly better than that in Fig. 4, and is somewhat better than that in Fig. 5; the same was true for L/D_e of 11.4. Consequently, the co-ordinates Y'' and X'' were employed for the final correlation. Fig. 7 shows that

L/D , entered to the minus 0.13 power. The recommended correlation of the local Nusselt numbers at the four values of L/D , is given in Fig. 8. The equation of the line is given by Equation [10], in which all physical properties are evaluated at the film temperature, t_f equals $(t_w + t)/2$. This equation correlates all the data, but should not be extrapolated outside the range of the data. At lower Reynolds numbers, modified streamline flow would prevail, and other dimensionless groups would be involved; at higher Reynolds numbers, the slope might decrease. At L/D , above 80, h may become asymptotic.

Values of viscosities were taken from reference (15), thermal conductivities were taken from reference (16), and the other properties were taken from steam tables (9). The range of values of μ_f , k_f and $c_{p\mu}/k_f$ for each pressure is shown in Table 2.

TABLE 2 RANGES OF PHYSICAL PROPERTIES

Pressure	t_f	μ_f	k_f	$(c_{p\mu}/k_f)$
115	518	0.0443	0.0240	0.95
	1011	0.0726	0.0525	0.79
500	606	0.0503	0.0294	1.01

2000	787	0.0639	0.0441	1.21
	1140	0.0859	0.0673	0.82
3000	951	0.0765	0.0551	1.03
	1116	0.0874	0.0665	0.88
3500	947	0.0774	0.0580	1.13
	1120	0.0893	0.0675	0.92

CONCLUSIONS

1 The use of electric heat developed in a thin-walled tube minimizes longitudinal conduction and permits measurement of local coefficients of heat transfer to steam flowing upward through a vertical annulus.

2 For a given Reynolds number and Prandtl number, the local Nusselt number always decreases as L/D , increases, regardless of the temperature at which the physical properties are evaluated.

3 For a given L/D , the method of plotting used in Fig. 6, with all physical properties evaluated at the film temperature, is distinctly better than that in Fig. 4, and is somewhat better than that in Fig. 5; the quantitative effect of L/D , from 11.4 to 80 is shown in Fig. 7.

4 The recommended correlation of all the data is shown in Fig. 8 and is given by Equation [10], which should not be extrapolated outside the range of data shown in Fig. 8. For a given Reynolds number the maximum deviation in the ordinate is 28 per cent, and the average deviation is 7 per cent.

Appendix

HEAT TRANSFERRED BY RADIATION

Since the present data were obtained for steam flowing in an annulus with an outer jacket that was colder than the flowing steam, an estimate was made of the net radiation from the heating element to the flowing steam and the outer jacket.

Professor H. C. Hottel of the Chemical Engineering Department at the Massachusetts Institute of Technology, derived an exact general solution of the problem by the method outlined by Hottel and Egbert (11). The result, a multiple-series equation, was too complex. A simplification, similar to the one used by Hottel and Egbert, gave the following equation

$$(q/A)_r = 0.173 \epsilon'_w \left\{ \left(\frac{T_w}{100} \right)^4 [\alpha_{L1} + (1 - \alpha_{L1}) \epsilon_j] \right. \\ \left. - \left(\frac{T_j}{100} \right)^4 \epsilon_j (1 - \alpha_{L2}) - \left(\frac{T_g}{100} \right)^4 \epsilon_{g L2} \right\} \dots \dots \dots [12]$$

where

- α = gas absorptivity for specified beam length and pressure
- ϵ_g = emissivity of steam for specified beam length and pressure
- ϵ_j = emissivity* of stainless jacket
- ϵ'_w = emissivity* of stainless heater at T_w
- ϵ'_w = effective emissivity of heating element equal to $(1 + \epsilon_w)/2$
- T_w, T_j, T_g = absolute temperatures of heating element, jacket, and steam, respectively, in deg Rankine
- $L1$ = effective beam length for gas radiation from heating element to gas
- $L2$ = effective beam length for gas radiation from gas to heating element

NOTE: Beam lengths $L1$ and $L2$ were assumed equal to 1.4 times clearance between heating element and jacket.

Since the present work was done at pressures far in excess of any for which gas-radiation data are available, the evaluation of the gas emissivities and absorptivities required an extrapolation of the existing data. Emissivities and absorptivities for gas

* The emissivity of stainless steel (14) was taken as a linear function of temperature, based upon 0.44 at 420 F and 0.36 at 914 F.

radiation (extrapolated to zero pressure were taken from Fig. 29 of reference (11), and were multiplied by the correction factor C_1 from Table 3, extrapolated from Fig. 30 of reference (11).

TABLE 3 - VALUES OF C_1

P , psia.....	115	500	1000	2000	3000	3500
P , atm.....	7.82	34.0	68.0	136	204	238
PL , atm-ft.....	0.119	0.515	1.03	2.06	3.09	3.60
C_1	1.85	1.75	1.65	1.50	1.45	1.42

As pressure increases C_1 decreases, but the emissivity at zero pressure increases faster than C_1 decreases; consequently the emissivity ($C_{1, \text{epw} = 0}$) increases. For example, at 1000 F, the emissivity increases from 0.156 at 115 psia to 0.568 at 3500 psia.

The simplified Equation [12] was shown to agree within 3 per cent of the exact equation for a typical case which was computed by both methods.

Addendum

Subsequent to the submission of this paper, new data on the thermal conductivity of steam became available through the courtesy of Prof. F. G. Keyes of the Department of Chemistry, M.I.T. The new data of Keyes and Sandell⁷ are shown in Fig. 9 of this addendum, for comparison with the earlier data of Timroth and Vargaftik (16) which were employed in the original correlation of Fig. 8. The new data have been extrapolated beyond a temperature of 660 F and pressure of 2200 psia by means of the correlating equation developed by Keyes and Sandell. The per cent deviation of the new data from the old becomes acute at high temperature, but is practically independent of pressure.

The new values of thermal conductivity were employed to recalculate all of the present data at L/D_e of 57. Plots of the recalculated data were made utilizing the parameters of Figs. 4, 5, and 6; the correlation of the type shown in Fig. 4 was very poor, that similar to Fig. 5 was fairly good, although the exponent on the Reynolds number was 0.71, and the best one was again the correlation employing film temperature similar to Fig. 6.

All the present data were then recomputed using the parameters of Fig. 6, and the effect of L/D_e was redetermined. The final revised equation, correlating all of the heat-transfer data and based upon the thermal conductivities extrapolated from the data of Keyes and Sandell is

$$\frac{h D_e}{k_f} = 0.0214 \left(1 + \frac{2.3}{L/D_e} \right) \left(\frac{D_e G}{\mu_f} \right)^{0.8} \left(\frac{c_p \mu_f}{k_f} \right)^{1/4} \quad [13]$$

As shown in Fig. 10 of the addendum, the maximum error is 17 per cent, as compared with 28 per cent for the correlation in Fig. 8.

⁷ "New Measurements of the Heat Conductivity of Steam and Nitrogen," by F. G. Keyes and D. J. Sandell, presented at the Annual Meeting, New York, N. Y., November 27-December 2, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Advantages of the revised correlation are (a) retention of conventional 0.8 power on the Reynolds modulus; (b) adoption of the fadeaway function for L/D_e , and (c) adoption of a value of 0.0214 for the constant in close agreement with established values at high L/D_e . It is worth noting that the fadeaway type of L/D_e correction could not have been obtained with the earlier value of thermal conductivity. The revised correlation is expected to be considerably better than the original one for purposes of extrapolation.

Further work remains to be done in extending the range of physical properties. Viscosities are still in question.

The authors desire to acknowledge the co-operation of Prof. F. G. Keyes in making his data available.

FIG. 1 PETTY ISLAND STOCK PILES PRIOR TO 1946

Philadelphia Electric Company Adopts Mobile Coal-Handling Equipment

By E. C. RUSSELL,¹ PHILADELPHIA, PA.

The paper covers the change from storing and reclaiming coal by cranes and locomotives to the use of standard self-propelled earth-moving equipment. The size and type of equipment are described, as well as its use. The change in design of storage piles is also considered. Description of new storage systems designed for the use of mobile equipment is presented. An analysis of operating costs and capacities is made with a comparison of the two methods.

THE Philadelphia Electric Company in 1946 began to make a complete change in its method of handling coal into and out of coal-storage piles. Coal stock piles are maintained for emergency use only and are reclaimed only when there is an interruption of the regular supply.

Coal is delivered normally to all but one of the six generating stations by barge, where it is unloaded by coal-tower clamshell-bucket installations. At the sixth station, barge facilities are not available and rail coal is unloaded into track hoppers.

¹ Supervisor, Coal Bureau and Steam Heating Division, Philadelphia Electric Company.

Contributed by the Power, Fuels, and Materials Handling Divisions and presented at the Annual Meeting, New York, N. Y., November 27–December 2, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49–A-63.

Prior to 1946 the company's method of coal storage was in piles between a system of parallel tracks. Fig. 1 shows the Petty Island coal-storage-plant stock piles prior to 1946. Fig. 2 is a recent view of the same location. These tracks were laid out on approximately 110-ft centers to give maximum height and width to the piles, using locomotive clam-shell cranes with 60-ft booms. This arrangement resulted in piles 100 ft wide and 30 to 35 ft high. On reclaiming, the cranes loaded into company-owned hopper cars. A locomotive switched these cars over track hoppers with a conveyer system which transported the coal to the normal bunker conveying system, or in the case of the Petty Island coal-storage plant, to a coal barge for transportation to a generating station. For storing coal, these same hopper cars were loaded at the coal tower by chutes fed by the coal-tower conveying system. A locomotive switched the cars to the storage yard, and the locomotive clamshell crane unloaded them.

CHANGE TO MOBILE EQUIPMENT

In March, 1946, we received the first piece of mobile coal-handling equipment on our initial order of three units. The other two units followed a short time later, and, by the end of the year we had acquired four more. Two more were put into operation early in 1949. These units are heavy earth-moving machines designed for construction work, self-propelled, bottom-loading, scraper type with four pneumatic tires. They have sufficient power to move their loads at relatively high speeds up

FIG. 2 PETTY ISLAND STOCK PILES FOR MOBILE EQUIPMENT

10 per cent grades and unload while moving, but need assistance in loading.

They are all Super "C" Tournapulls with Model LP Carryall scrapers, manufactured by R. G. LeTourneau, Inc., Peoria, Ill. The engines are 4-cycle 6-cylinder Diesel engines. Five of the nine are 150-hp Cummins engines, while the other four are 124-hp Hercules engines. The maximum speed of these units is 14.3 mph. The scraper capacity is 12.1 cu yd; heaped it has a 15-cu-yd capacity.

On the reclaiming cycle, we average $8\frac{1}{2}$ to 9 tons per load. On the storing cycle, since they are loaded by an overhead chute, a pant-leg-type hopper had to be designed to straddle the operating mechanism directly over the center line of the bowl of the scraper. This increases the tonnage per load on storing to 11 tons. Fig. 3 shows one of the units.

Self-propelled units have the advantage of the greater speed on the longer hauls and are usually more economical than the crawler-tractor-drawn scrapers on hauls over 600 or 800 ft on earth-moving work. However, the self-propelled units are favored even on the shorter hauls, for unlike most earth-moving work they are mechanically loaded when storing coal which theoretically is 50 per cent of their operation.

Self-propelled units being rubber-tired vehicles have the added advantage of being better-suited for use around paved station yards. They are also readily transferred over the road under their own power to another location. At times it is advantageous to be able to transfer a unit from one station to another to assist in the movement of coal.

TRACK-TYPE BULLDOZERS USED

Since the inception of mobile coal-handling equipment we have purchased four track-type bulldozer tractors. They are all Oliver Cle-Trac Model FDE with 130-hp Hercules Diesel engines. This is the largest tractor Oliver Cle-Trac make and is comparable in size to the International TD 18 or the Caterpillar D8. All four tractors are equipped with bulldozer blades as well as a power control unit on the rear. The power control unit is used to cable-operate a drawbar for towing the scrapers to assist loading on the reclaiming cycle.

The scrapers are equipped with a pusher pad on the rear for pusher-loading by a bulldozer. However, we have established a definite policy of not using this method of loading because our self-propelled scrapers are clutch-steered on the driving wheels. This presents the possible hazard of jackknifing if the bulldozer

FIG. 3 SCRAPER SHOWING PANT-LEG HOPPER

FIG. 4 TRACTOR DRAWBAR ENGAGING SCRAPER HOOK

is pushing faster than the scraper engine is driving it. Also there is some possibility of the bulldozer blade cutting a rear tire of the scraper if proper contact is not made. It is felt that our method of loading has the added advantage of leaving the scraper operator's hands free to operate the power control unit, and his attention therefore can be directed toward the loading of his machine, since the tractor is towing, and thus guiding its direction. Later models of Tournapulls have positive steering, and likely there are advantages in push-loading them.

One other point in connection with the clutch-steering model is that the ramps or inclines on the storage piles should be straight if possible, especially if the change is being made to this method of storage, and men are being trained in the operation of this equipment. This is mentioned because it is necessary to have power on the driving wheels for steering; if the practice is to coast down the incline with the engine idling, it is necessary to reverse clutch or "cross-steer." This of course is no problem for experienced operators.

The drawbars used for towing or snatch-loading are approximately 16 ft long with a 24-in. eye in a horizontal plane on the outboard end to engage a hook, mounted point down on the front end of the engine frame at the bottom. Fig. 4 shows a bulldozer preparing to snatch-load a scraper. The oil pan of the engine crankcase is protected with heavy plates so the eye can slide onto the hook. The drawbar is raised and lowered through a series of cables and sheaves by the power control unit on the rear of the tractor. Thus the scraper to be loaded drives up to the rear of the tractor in line with the drawbar. The drawbar is raised by the tractor operator, and upon engagement the tractor starts its tow. The operator of the scraper then concentrates upon the operation of the power control unit which raises the gate and lowers the bowl of the machine. When loaded, he lowers the gate, raises the bowl, speeds up, and turns to avoid the tractor, at the same time the tractor operator is lowering the drawbar.

METHOD OF STORING COAL WITH MOBILE EQUIPMENT

The method of storing coal with mobile equipment is entirely different from old methods with locomotive cranes. The Philadelphia Electric Company made the change-over to mobile equipment at an opportune time. Due to mine strikes, the coal stocks in 1946 were reduced to the lowest level at any time in the preceding 12 years. Thus we were able to remove the parallel tracks and relocate essential trackage where necessary, so that stock piles could be laid to the best advantage for this type of equipment.

It is readily apparent that one of the advantages of this method of storage is the increased quantity that can be stored on the same area. The parallel piles with the tracks between reduce the volume by approximately 50 per cent.

Figs. 1 and 2 show a very good comparison of the two methods of storing coal. The piles in Fig. 1 total approximately 150,000 tons of coal. The three piles shown in Fig. 2 total approximately 180,000 tons. It is quite apparent they have not even approached their maximum height. Close study of the two illustrations also will reveal that the piles in Fig. 2 extend possibly only one half the distance in the background compared with the piles in Fig. 1.

Furthermore, with mobile equipment, piles of much greater height are possible. Scraper-type equipment is ideal for storing coal, since this method of unloading allows the coal to be laid down in thin layers. Rolling or any other method of compaction as a fire preventive is not necessary as the mobile equipment with its large pneumatic tires has increased the density in our piles from 60 to 69 lb per cu ft. The old method of packing was to run a small crawler tractor, dragging a section of railroad rail on a bridle over the pile constantly while storing coal. We still follow this practice with the large tractors, but to a much lesser extent, and then only to maintain a fairly level surface, and to pack and spread the extreme edges of the pile where a self-propelled unit might encounter difficulties from its outside wheels sinking in the soft edges.

On the reclaiming cycle, the top of the pile is scraped off as evenly as possible, leaving the pile in shape for the time when coal is restocked again. One tractor will take care of the loading of two scrapers on the shorter hauls, while on the longer hauls three machines can be used.

Where possible, piles should be laid out with the ultimate tonnage desired in mind; so that the top of the completed pile will be as small as possible and still allow sufficient maneuverability for mobile equipment. This is essential because, in any case, there is a relatively large area of hard-packed coal, and the run-off of rain water resulting from a heavy downpour may be quite large. Provisions for handling this run-off should be made. If the top of the pile is made saucer-shaped, then the end result may be a small lake. At times of reclaiming, obviously, this is not desirable. The difficulties of handling wet coal in the usual chutes and conveyer systems, as well as the problems of burning extremely-wet coal are well known. We have had some success in grading the top toward one or more wooden chutes to lead the water down the side of the pile. These chutes require attention

occasionally, especially after a heavy rain. It is interesting to note that it has been found necessary to calk all cracks and keep the chute absolutely watertight or a serious washout beneath the chute may result.

In changing to mobile equipment the weight of the loaded unit must be considered if there are light paving slabs, manhole structure, or underground facilities too close to the surface. Also, in locations of limited area, minimum maneuvering space should be studied. The scrapers on our system will turn in a space 40 ft wide; however, we prefer a minimum width of 60 ft to improve maneuvering time.

The reclaiming of finer sizes of coal from the highly compacted piles made by mobile equipment has at times given some trouble with poor flow of coal in the pipes from bunkers to pulverizing mills and stokers. Former troubles in the stoker hoppers have been eliminated by the installation of agitators.

COAL-HANDLING FACILITIES

The Philadelphia Electric Company has stock piles at four generating stations, and a coal-storage plant on an island in the Delaware River. Petty Island—the coal-storage plant—serves the two stations without storage facilities by barge, and supplements the reclaiming at the other stations when necessary.

The change-over to mobile equipment required very little change in coal-handling facilities. The track hoppers in all locations had to be covered with some form of heavy steel grating designed to carry the load of a scraper. With the large-diameter wheels this grating can be made quite open.

On new installations, facilities are designed for the use of mobile equipment. At our Barbadoes Island Station where additional generating capacity was recently added, completely new coal-handling facilities were designed and installed for mobile-equipment use. This is the one station which must rely on rail coal delivery. The coal-unloading shed and track hoppers are laid out for the reclamation of coal by mobile equipment. The average haul distance is approximately 500 ft.

For storing coal, a scraper loading hopper was included in the design. This is a hopper of 20 tons capacity fed from the bunker conveying system so that a scraper can be loaded quickly without waiting for the normal flow of the 250 tons per hr of the conveying system, which would require approximately 3 min for loading. The haul distance for storing coal is approximately 400 ft.

A new coal-storage yard with an ultimate capacity of 1,000,000 tons is now in the planning stage. It is being designed to have a scraper loading hopper of 250 tons capacity and an ultimate rate of 500 tons per hr stocking by mobile equipment. For reclaiming, it is planned to have two unloading hoppers of 50 and 25 tons capacity, respectively, and a reclaiming rate by mobile equipment of 700 tons per hr.

ANALYSIS OF OPERATING EXPENSE

An analysis of the various accounts involving the storing and reclaiming of coal, and the operation and maintenance of cranes, locomotives, and mobile equipment reveals some interesting figures. However, these figures must be analyzed in the light of our operating conditions and accounting methods.

Three accounts were analyzed for the years 1944, 1945, 1947, and 1948. The year 1946 was excluded since that year involved the transition period from the old method of handling coal to the present method. The three accounts analyzed were (1) crane expense, (2) storing coal, (3) reclaiming coal.

It should be noted that the operating and maintenance expenses of a locomotive or locomotive crane is charged to the crane account regardless of its use. Some are regularly used by the Gas Department for handling coke, coal, and ashes, while others are digging ashes and slag as well as handling coal at the various

generating stations—or making occasional lifts of heavy equipment.

The crane account was analyzed in order to establish an average actual cost per hour of use for operating and maintenance expenses.

The storing and reclaiming coal accounts were studied to determine the hours of equipment operation and the tons of coal handled.

One year of the maintenance account on the cranes was analyzed completely to determine the ratio between material and maintenance labor so that the various years could be adjusted to 1948 costs by material and labor indexes. It was found that approximately 40 per cent of the account was material, and the remaining 60 per cent was maintenance labor. This agrees favorably with studies that have been made on generating-station maintenance accounts. Therefore it was assumed these figures would hold true for all years.

The maintenance labor costs of the various years were adjusted to 1948 costs by labor factors which have been established on actual conditions in the company. Materials in the maintenance account were also adjusted to 1948 costs by a materials index. A cost per hour of operation adjusted to 1948 costs was then derived for the cranes and locomotives for 1944 and 1945, and for the scrapers and tractors for 1947 and 1948.

These costs per hour of equipment use were then applied to the respective year's hours of equipment use on reclaiming and storing coal at two different locations. The two years for each method of operation were then combined to give weighted average costs.

Table 1 gives the comparison between the old method of using cranes and locomotives and the new, using scrapers and tractors, for both reclaiming and storing coal at the Petty Island coal storage plant. Table 2 is a similar tabulation for handling storage coal at Richmond Station.

TABLE 1 COMPARISON OF OLD AND NEW METHODS AT PETTY ISLAND PLANT

	Tons (1)	Tons per hr (2)	Equip- ment cost, dollars per hr (3)	Equip- ment cost, cents per ton (4)
RECLAIMING COAL

Mobile equipment.....	26066	60.2	3.50	5.8
STORING COAL				
Cranes and locomotives.....	63399	47.9	3.39	7.1
Mobile equipment.....	210009	74.2	3.43	4.6

TABLE 2 COMPARISON OF OLD AND NEW METHODS AT RICHMOND STATION

RECLAIMING COAL				
Cranes and locomotives.....	85856	43.6	3.33	7.6
Mobile equipment.....	140176	43.3	3.35	7.7
STORING COAL				
Cranes and locomotives.....	90839	35.1	3.36	9.6
Mobile equipment.....	186825	69.8	3.39	4.9

Referring to the tables, column (1) is the tons of coal handled. Column (2) is the tons per hour handled. Column (3) is the weighted average cost per hour of equipment use. Column (4) is equipment cost per ton of coal handled. All figures are a weighted average for the two-year period for the respective equipment.

To be explicit, the 87,519 tons in column (1), Table 1, are the total tons of coal reclaimed during 1944 and 1945, at Petty Island. Column (2) is the tons in column (1) divided by the hours of operation in the two years. The 3.38 dollars in column (3) are the result of dividing the total of 1944 and 1945 equipment expense by the total hours of operation for the two years. Column (4) is the total equipment expense divided by the tons of column

(1). Column (3) divided by column (2) will of course also produce column (4).

The same procedure was followed for the scrapers and tractors for the years 1947 and 1948.

It is apparent from column 3 of either table that the equipment cost per hour is practically the same for the two types of equipment. This was also found to be the case when the total 1944 and 1945 crane and locomotive account for the 28 pieces of equipment on the entire system was averaged and compared with a similar 1947 and 1948 figure for the 7 scrapers and 4 tractors. The two figures were 3.39 and 3.38 dollars, respectively, or so close that it would appear to have been intentional.

However, on comparing the results in either table for the two types of equipment, it is seen that the tons per hour handled are 25 per cent to 100 per cent greater than with the old method, with one exception, that is, reclaiming coal by mobile equipment at the Richmond Station.

It must be understood that the tons per hour in column (2) for either reclaiming or storing coal are per equipment-hour including tractors as well as the scrapers. For instance, on the reclaiming cycle we will have to assume that the normal method of operation was one tractor and two scrapers. To find the approximate scraper tons per hour the 60.2 tons on the second line of column 2 of Table 1 will be three pieces of equipment times 60.2 divided by two scrapers, or an average of 90.3 tons per hr reclaimed per scraper. However, on the storing cycle, the tractor is not usually used full time, hence the same ratio does not hold.

The foregoing partially explains the greater tonnage per hour moved on the storing cycle compared with the reclaiming cycle. Another factor is the 2 to 2½ tons or approximately 25 per cent greater capacity of the scrapers when storing coal. On the reclaiming cycle, too, a little more time is consumed on the pile loading the scrapers than in loading them to haul to the storage pile. Likewise, in discharging their load in the hoppers when reclaiming, the machine must come to a complete stop, but, when storing, the discharging is done on the move, and the machine continues on its route back to reload. The advantages of the self-propelled unit on storing are quite obvious regardless of the length of haul.

The low tons per hour reclaiming rate at Richmond Station as compared to the Petty Island operation is due to several factors, as follows:

- 1 The reclaiming hoppers at Richmond Station are not of sufficient capacity for mobile-equipment use. They are truck hoppers for unloading railroad hopper cars and are now in the process of being rebuilt with a greater capacity.

- 2 Operating conditions at the two locations are not the same. Petty Island is strictly a coal-storage plant and, when reclaiming, loads barges of as much as 2400 tons capacity. Richmond, being a generating station, reclaims the coal demands of the station. This station also burns two kinds of coal—stoker and pulverized—

and has two bunker belts in each bunker. Thus many times during a day of reclaiming there are short delays due to changing over bunker belts, changing from one bunker to the other, which also means changing from one storage pile to another. Furthermore, reclaiming stock coal, especially if wet, always causes some operating difficulties with conveyer systems. It cannot be expected under those conditions to deduct these short interruptions from the over-all equipment operating time. Hour meters installed on each machine would of course give the actual hours of operation.

It must also be pointed out that the total equipment-hours for either reclaiming or storing which were used to arrive at the hourly rate figure may include some nonproductive hours in so far as tons moved into or out of stock are concerned; since it is necessary at times to use the equipment to regrade a pile after considerable coal has been removed, or to clean up after a heavy rain may have damaged a pile. This time would be charged to one or the other accounts. Thus the data in the two tables are over-all figures for the two-year period and include all the equipment time relative to stock piles.

We know from several spot checks for periods ranging from 1 hr to a full day's work that a scraper is capable of reclaiming 70 to 90 tons per hr and will store better than 100 tons per hr.

A real saving in the use of mobile equipment is the resulting laborsaving. Formerly at Richmond Station it was necessary to use two cranes and a locomotive, and work longer hours at overtime rates to supply the demands of the station. This would require two engineers and two firemen for the cranes, an engineer for the locomotive and a brakeman, a total of six men. Stocking coal, one additional man would be required to pack and spread the coal with a tractor. Today, with mobile equipment more coal is reclaimed or stocked with but three men, namely, two scraper operators and one tractor operator. Furthermore, it takes far less time to train a scraper operator than a crane operator.

CONCLUSION

In conclusion, we feel that mobile coal-handling equipment is ideal for our conditions and methods of operation. For the first two full years of operation it has proved to be sound from an economy standpoint. We feel that the equipment is much more versatile than our former equipment for handling storage coal. If we find it necessary to store or reclaim coal on short notice it doesn't seem like the major operation that it appeared to be previously.

Finally, it must be remembered that mobile equipment is built primarily for earth moving and not for coal handling. Since coal is approximately one half the density of earth, it means that scrapers should be able to carry a considerably greater volume of coal than they are capable of handling. Therefore, from the standpoint of the buyer of equipment for coal-handling, improvements could be made.

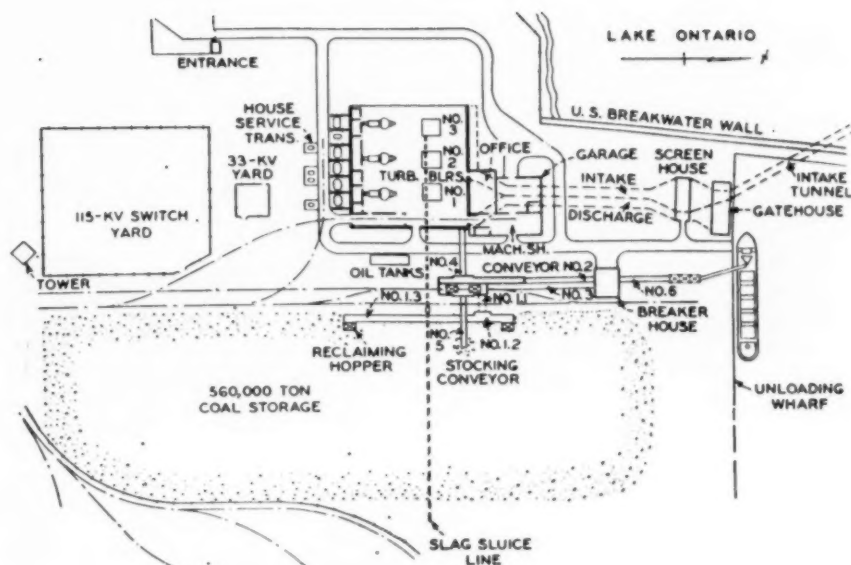

FIG. 1 PLAN OF COAL-HANDLING SYSTEM, OSWEGO STEAM STATION

Storing and Reclaiming Coal With Earth-Moving Equipment at the Oswego Steam Station

By J. N. EWART,¹ BUFFALO, N. Y.

Earth-moving equipment at the Oswego Steam Station of the Central New York Power Corporation has handled in excess of 3 billion ton-feet of coal during its first 9 years of operation. Coal is stored in a single pile 100 ft high with no danger of spontaneous combustion. The paper describes the operation of bulldozer-carryall units and presents operating and maintenance costs.

GENERAL DESCRIPTION

THE coal-handling system of the Oswego Steam Station of the Central New York Power Corporation is a simple one and lends itself readily to expansion of the station. Fig. 1 is a plan of the coal-handling system, showing the location of the storage pile and its relation to the receiving and reclaiming points. It also shows the arrangement of belt conveyers which permit

movement of coal to the house coal bunkers or to and from storage from either track hoppers or self-unloading lake boats.

Although provision is made for either rail or lake delivery of coal, all coal is received by self-unloading boats which discharge directly to either a receiving hopper or to one end of a 1400-ft-long \times 400-ft-wide stocking pile. This pile often reaches a height of 100 ft on the high end and has contained as much as 560,000 tons of coal, Fig. 2. From the receiving hopper the coal is carried through a Bradford breaker direct to the house coal bunkers or to a stocking conveyor, equipped with a telescopic chute which discharges to the stocking pile about 300 ft from the wharf end.

STOCKING AND RECLAIMING OPERATION

The coal is moved into storage from the discharge of the self-unloader or from the stocking pile entirely by means of bulldozer-carryall unit. During the stocking operation a bulldozer-carryall unit makes a round trip of approximately 2000 ft every 10 min. This trip starts at the stocking pile where the carryall picks up its load of 13 tons, carries it an average of 700 ft to the spreading area, and lays it down in a ribbon approximately 13 ft wide, 40 ft long and 10 in. thick, and then completes the circuit by returning for another load. Subsequent trips pack this ribbon of coal and integrate it with the rest of the pile to produce a section which is nearly impervious to air and water. Test pits have

FIG. 2 COAL STORAGE PILE 100 Ft HIGH LOOKING EAST FROM GATE HOUSE

FIG. 3 AERIAL VIEW OF TOP OF STORAGE PILE DURING A STOCKING OPERATION

indicated that this coal is packed to densities of 80 lb per cu ft.

Fig. 3 shows the operation on the top of the pile during stocking. There have been no fires in this coal pile to date and sections of it have stood untouched for as long as 3 years.

Oswego's experience would indicate that many of the usual rules for successful storage of coal can be violated if coal is laid down in thin layers and adequately compacted. For example, no effort is made to avoid segregation though coal may be purchased from 60 mines varying in volatile matter from 17 to 37 per cent and sized from fine slack to double-screened and run of mine. Sulphur varies from 1 to 3 per cent. No particular effort has been made to provide a hard base or adequate drainage for the foundation, and there is no limit to the height of the pile.

Coal is reclaimed entirely by means of the bulldozer-carryall

units. Two reclaiming hoppers are located along the lengthwise toe of the storage pile, 300 ft apart. Additional hoppers can be provided if necessary to reduce the reclaim hauling distance. In reclaiming coal from the stock pile the coal is removed, in so far as possible, by working it off in vertical layers starting from one end of the pile. In this way the top surface of the pile is disturbed the least, and the nearly vertical surfaces which are exposed will absorb practically no water or snow. The coal is packed well enough that nearly vertical sides have been formed 40 ft high with no experience of a cave-in.

Since all of the coal is received by boat and, therefore, a year's supply must be obtained during the favorable navigation season of approximately 6 months, there is necessarily considerable movement of coal in and out of the storage pile over the period

FIG. 4 TRACK HOPPER BUILDING AND JUNCTION TOWER, OSWEGO STEAM STATION

of a year. For example, the total movement of coal in and out of storage for the 9-year period was 5,225,000 tons, compared with an amount burned during this period of 3,600,000 tons.

OPERATING DATA

Table 1 shows the operating and maintenance cost of the bulldozer-carryall equipment in dollars per 1000 ton-feet by years, covering the period 1945 to 1948, inclusive. Comparable information prior to these years is not available.

TABLE 1 BULLDOZER-CARRYALL OPERATING AND MAINTENANCE COST DATA AT OSWEGO STEAM STATION

Year	Total coal handled, tons	Dollars per 1000 ton-feet				
		Operation Labor	Fuel	Maintenance Labor	Material	Total
1945	614080	0.046	0.006	0.026	0.020	0.098
1946	444894	0.067	0.006	0.035	0.011	0.119
1947	700986	0.063	0.006	0.026	0.010	0.105
1948	828985	0.064	0.008	0.032	0.021	0.125
Average		0.060	0.006	0.030	0.016	0.112

Figures are shown in Table 1 on the basis of ton-feet in order to consider the length of the haul as well as the tonnage in arriving at the unit costs. It is recognized that there is not necessarily a straight-line relationship between cost and hauling distance. The incremental cost for distance, once the carryall is loaded and under way, may be relatively small. Using the average total value of 0.112 per 1000 ton-feet for the 4 years, it may be seen that Oswego's 700-ft out-haul cost was 7.8 cents per ton, and the 500-ft reclaiming cost, 5.6 cents per ton. It is believed that the maintenance cost of this equipment has reached its leveling-off value, except for possible increase in labor rates and material, since, at the end of 1948, the average life of the bulldozer-carryall units was 7 years, and a continuing program of replacing the older units has been developed.

It is interesting to note that one bulldozer handled approximately 500 million ton-feet before retirement.

INVESTMENT COST

The foregoing operating costs are exclusive of fixed charges on the capital investment. One of the advantages of mobile equipment, as compared with permanently installed machinery for handling storage coal, is that the initial investment can be small, and only that which is required for the initial installation. As and if the station expands, the storage area and coal-storage equipment can be expanded as required and always with modern equipment. Much in the way of improved and more efficient mobile equipment for handling coal has been developed in the last 5 years, and further improvements are inevitable.

Table 2 shows the capital investment in mobile equipment by years for the Oswego Station. Note that the initial investment was very small for the first few years of two-unit operation and increased as additional units were added. The original installation at Oswego consisted of two 80,000-kw rated, 100,000-kw maximum turbogenerator units with steam conditions of 1250 psi, 900 F. Each unit is supplied by a single boiler rated at 900,000 lb per hr. The third unit, essentially a duplicate of the first two, went into service in December, 1948. Installation of the fourth unit is now in progress and scheduled to be in service in 1951.

TABLE 2 CAPITAL INVESTMENT IN MOBILE EQUIPMENT AT OSWEGO STATION

Year	Station capacity, kw	Capital investment	Bulldozer units	Carryall units
1940	80000	\$54780	3	2
1941	160000	54780	3	2
1942-1947	160000	65544	4	2
1948	240000	73143	4	3

Fig. 4 is shown to emphasize that the coal-handling structures and even the coal pile itself can become not too unsightly if proper consideration is given to architectural lines and landscaping, followed by a desire on the part of the station operators to maintain a good appearance of the buildings and grounds.

Vibration of Marine-Turbine Blading

By R. W. NOLAN,¹ NEWPORT NEWS, VA.

The purpose of this paper is to give a general explanation of the vibration phenomena encountered in turbine design. Detailed methods have been omitted. The behavior of a vibrating cantilever is expressed in terms of the exciting force and damping factor. The sources of damping and excitation are discussed. Impulse excitation is briefly considered and the reasons for its devastating effects are shown. The procedure of tuning low-pressure blading, to avoid resonance at the lower harmonics of the turbine speed, is explained in considerable detail. An apparatus for determining the natural frequency of blading, and another for applying both tensile and alternating bending stresses simultaneously, are described. The direct tensile stress in the test is plotted versus the alternating bending stress which causes failure, thus obtaining a curve which shows the resistance of the blade to any combination of these stresses. The designed stresses for certain turbine blades and the stresses involved in several blade failures have been plotted on this diagram for purposes of comparison.

GENERAL

IN recent years there has been a demand for decreased fuel consumption and a decrease in weight and space requirements for marine machinery. This of course had to be accomplished with no sacrifice in reliability because machinery failure can, on some occasions, endanger the life of the ship. The result of this demand has been a trend toward small high-speed turbines.

In the case of the high-pressure turbine, little difficulty was encountered in increasing speeds and a very rugged machine has been obtained. The low-pressure turbine, on the other hand, presents a complicated problem. The volume of steam passing through the last rows of blading is determined mainly by the horsepower and vacuum. This in turn approximately determines the diameter for the last blade row. With the diameter determined, the speed in revolutions per minute is then governed by stress considerations. The blade is made as long as possible to obtain maximum area for the steam passages, but its height is limited by considerations of stress and vibration. The blading in the last few stages is a compromise governed by steam flow, vacuum, efficiency, wheel stress, blade stress, and vibration.

At this point it should be mentioned that the last few rows of blading are not the only ones which can give vibration trouble. They are, however, the most susceptible to it and are the ones on which most vibration studies are concentrated. It is usually assumed that turbine blades are subjected to steady forces. Actually, this is not entirely true. All turbine blades are subject to certain variations in force. In the great majority of cases these force variations do no harm. Occasionally, however, the vibration characteristics of the blade might be such that a dangerous vibration could be set up by the exciting force variations which

are always present in the turbine. It is the duty of the designer to see that this does not happen.

BEHAVIOR OF BODIES SUBJECTED TO VIBRATORY FORCES

Before proceeding with specific turbine problems, it is desirable to review briefly the behavior of a simple vibrating structure, and to define the terms which will be used. For this purpose, consider a steel cantilever beam of constant rectangular cross section 2 in. \times 1/2 in. and 12 in. in length. These scantlings have been chosen because they give characteristics which are not too far from those of a low-pressure exhaust blade. Assume further, that this beam is subjected to a force which varies sinusoidally with a maximum value of 0.6 lb uniformly distributed over the broad side.

The behavior of the beam subjected to this force is shown in Fig. 1 in which the amplitude of vibration at the end of the blade is plotted as a function of the frequency of the applied force. At frequencies approaching zero, the amplitude of vibration is 0.000208 in. which is equal to the static deflection produced by a force of 0.6 lb. As the frequency of the exciting force is increased, the amplitude increases until it theoretically reaches infinity at 6800 cycles per minute (cpm) (following the solid curve). Above this frequency the amplitude drops sharply. If the frequency of the exciting force were increased sufficiently, the amplitude would be found to approach infinity again at 42,600 and 119,500 (cpm) and at still higher values.

The frequencies at which the amplitude reaches infinity are the natural frequencies of this blade. The natural frequency at 6800 cycles is the first critical or first mode and that at 42,600 cycles is the second critical or second mode. The turbine designer is usually interested only in the first mode. The term "resonance" is used to describe the action which takes place when the frequency of the applied force coincides with a natural frequency. The terms "resonant" frequency and "critical" frequency are frequently used for natural frequency.

The curve under consideration is based on the assumption that there are no losses of energy in the vibrating system. Such a condition would be the equivalent of perpetual motion. Actually, frictional forces are always present, and it is fortunate that they are. Otherwise all turbines would strip out their blades in a relatively short time.

In vibration problems the frictional resistance to vibration is expressed frequently as a damping coefficient.² The dotted curve in Fig. 1 shows the behavior of this same blade with a damping coefficient of 0.10. At resonance, the amplitude of the first

FIG. 1 VIBRATORY RESPONSE OF A CANTILEVER BEAM

FIG. 2 VIBRATORY STRESS IN A CANTILEVER BEAM

critical (at 6800 cycles) is 0.00208 which is 10 times the amplitude at low frequencies.

For each deflection which is shown in Fig. 1, it would be possible to calculate the moment and stress in the material. This has been done in Fig. 2. At low frequencies the stress of 43.2 psi is equal to that produced by the exciting force of 0.6 lb acting statically. At other frequencies, the stress is proportional to deflection, and at resonance it amounts to 432 psi, or 10 times the stress at low frequency. The factor 10 is the magnification factor. It is equal to the reciprocal of the damping coefficient.

This method of applying the magnification factor to the static deflection applies strictly to a concentrated mass on a weightless spring. Its application to deflection and stress of a turbine blade is an approximation which is sufficiently accurate for first-mode vibrations. It is not necessarily suitable for higher modes or for other types of structure.

Those familiar with alternating-current theory, will recognize these curves to be the same as those obtained with resonant electric circuits. Magnification factor shown here is the same as the Q -factor which applies to series resonance in an electric circuit. The stress of 432 psi may appear low. It is low because a relatively high damping coefficient was used, in order to obtain a resonance curve which would plot well on a lantern slide. In actual turbine blades, the damping coefficient may be 0.005. This gives a magnification factor of 200 which would make the foregoing stress equal to 8640 psi.

CAUSES OF DAMPING IN A TURBINE

The factors which produce damping in turbine blades may be classified as elastic hysteresis, steam damping, and rubbing friction. Elastic hysteresis is internal friction in the blade material as it goes through the stress cycle. It varies widely with composition of the material and with temperature. It is difficult to determine experimentally; several investigators do not agree very well on the values. There is, however, enough information to permit a rough determination of the damping coefficient.

Another cause of damping is the resistance of the steam surrounding the blade. A rational method of determining the magnitude of steam damping would be to treat the velocity of vibratory motion as a change in blade speed, and to calculate the resultant change in tangential steam force. Application of this method shows the resultant damping forces to be rather small (less than hysteresis damping), and they usually are neglected.

The third cause of damping is rubbing friction between surfaces. There is always some minute sliding at the points of contact between the blade and the rotor, and between adjacent blades. The value of this damping is extremely variable, depending upon the design and on the fit which is obtained. Blades which are packed tightly together and are fitted accurately with considerable press fit, will have low frictional damping. Blades which are loose in the groove, or which are poorly fitted may have very high damping. In such cases the frictional damping will be many times that obtained by steam and hysteresis. This can be observed easily by striking the blades of a turbine rotor. Tight blades will ring clearly for a considerable time after striking. If the blades are loose, they have a dead sound because the vibratory energy is damped out almost immediately after striking. A natural reaction to this fact would be the suggestion that blades be installed loose to prevent vibration. This expedient might well be successful but one would hesitate to install loose blades, because of the possibility of wear caused by the movement. Furthermore, a blade which is poorly fitted may sometimes have its natural frequency lowered so that it falls into a resonant condition. It also may fail in the root, while tightly packed blades could not fail this way because they do not bend below the packing piece. Because of the uncertain nature of frictional damping, it is neglected in calculations.

A possible fourth source of damping is impact. It is closely related to frictional damping and may occur to some extent between adjacent faces of blade roots. There are patents on devices such as hollow blades containing loose rods or balls which are intended to cause impact damping if the blade vibrates. It is doubtful that these will ever find extensive application to marine turbines.

It thus appears that elastic hysteresis is the most dependable source of damping. Fig. 3 shows curves of the magnification

FIG. 3 MAGNIFICATION FACTOR FOR STAINLESS STEEL

factors of 13 and 14 per cent chromium stainless steel. These curves, based on data from an article by Andrew Gemant,³ are expressed as a function of the vibratory stress.

³ "Dependence on Stress of Damping Capacity of Alloys," by Andrew Gemant, *Mechanical Engineering*, vol. 67, 1945, p. 33.

EXCITING FORCES ACTING ON TURBINE BLADES

It was mentioned previously that there are always variations present in the tangential steam forces acting on blades. These may be due to many causes. Among them is the variation of pressure around the periphery of the wheel. Pressure variations cause variations in the steam velocity acting on the blade. These variations are difficult to measure experimentally because of the large number of pressure readings which must be obtained. Fig. 4, however, shows an approximate curve of pressure variation based on measurements at five points around the periphery of the last low-pressure stage of a turbine. One curve shows the discharge pressure and the other the inlet pressure for this stage. The last curve shows the variation in the Btu drop in the stage. In this case the maximum variation was about 12 per cent of the average heat drop. This is probably an extreme case since it is the last stage of a heavily loaded turbine.

Similar effects will be found at any point in the turbine where steam is being admitted or extracted. Designers frequently go to considerable pains to distribute steam uniformly in bleeder belts, chests, inlet belts, and in the space between the high-pressure first and second stages. In spite of their best efforts variations still exist.

Lack of uniformity in nozzles or blading also may be a source of uneven steam force. The discontinuity at the horizontal joint in the casing is a further possibility. It is difficult to keep the spacing of the nozzles, which span the joint, the same as that in the remainder of the ring. The conditions at the joint then may result in a different size of nozzle jet and, possibly, a different discharge angle. The blade rotating past these points will experience two impulses at each revolution.

The most severe form of excitation which occurs in turbines is known as impulse excitation. It usually occurs only in the high-pressure first stage and in astern turbines. In these stages steam is admitted to the wheel over a portion of the periphery, usually less than 180 deg. As the blade rotates, it enters the steam arc, receiving a sudden application of the full steam force. When it passes out of the steam arc, the sudden removal of the steam force is equally severe. The force variation is thus equal to 100 per cent.

Fortunately, the blades which receive this punishment are among the shortest and most rugged in the whole turbine. In spite of this, impulse excitation has been a serious problem to shore power plants, and it resulted in a number of failures before the cause was discovered. The shore turbines which suffered these breakdowns were high-pressure topping turbines which used large quantities of high-pressure high-temperature steam (1200 psi, 950 F). Conditions as severe as this have not yet been imposed on marine turbines and therefore failures of first-stage blading have been few. Present trends in marine steam conditions may bring on this trouble, and the designer must be alert to avoid it. A mild form of impulse excitation might be set up by damage which would partially close some of the nozzles in any turbine stage.

Blade vibration also may be excited by external forces. In one case, blade failure in a small geared turbogenerator was attributed to vibration set up by errors in the gear-tooth spacing. It is also possible that errors in the roundness of the journal may cause a motion which could set blading in vibration.

With the exception of impulse excitation, our knowledge of the magnitude of exciting forces is quite limited. We do know, however, that they are present in sufficient magnitude to cause failure of improperly designed blades. The uncertainty concerning the exciting forces and, to a considerable extent, the damping forces has led some of the large turbine manufacturers to adopt an empirical approach to the problem.

HARMONIC ANALYSIS OF EXCITING FORCES

Regardless of what may be the pattern of the exciting forces, it will be repeated periodically, usually once for each revolution of the turbine. Any periodically varying set of values, such as the exciting forces acting on a turbine blade, can be broken up into a series of sine and cosine curves. The frequencies of these harmonic components will be integral multiples of the frequency of the original curve.

For example, take the lower curve in Fig. 4, showing the distri-

FIG. 4 PRESSURE AND HEAT DROP IN A TURBINE EXHAUST STAGE

FIG. 5 HARMONIC ANALYSIS OF FORCE VARIATION IN A TURBINE EXHAUST STAGE

bution of heat drop around the circumference of the wheel. Assuming that the steam force, acting on a blade, is proportional to the heat drop, a curve of force variation has been plotted in Fig. 5 (solid curve). Each blade will be subjected to this force variation at each revolution.

By applying a Fourier analysis, the first four harmonics have been obtained. These also are shown in Fig. 5 (dotted curves.) Their amplitudes and phase angles are given in Table 1.

TABLE 1 AMPLITUDES AND PHASE ANGLES

Harmonic	Amplitude, per cent	Phase angle, deg
1	10.1	+253
2	4.1	+206
3	1.1	+24
4	0.6	+3

There was no justification in carrying this analysis beyond the fourth harmonic because there were so few points on the original curves from which the drop was calculated. It should be observed how the harmonics decrease in amplitude as their order increases. This is generally to be expected but it is not always so.

To illustrate the exciting forces generated by impulse excita-

tion, the diagram shown in Fig. 6 has been assumed. Here the nozzle arc is assumed to be 90 deg with instantaneous application and removal of the load taking place at the ends of the arc. The

FIG. 6 STEAM-LOADING DIAGRAM FOR HIGH-PRESSURE FIRST-STAGE BLADING

instantaneous application and removal of the load is a rather severe assumption, but it is much less tedious to apply and therefore is more convenient for preliminary design purposes. Analysis of this diagram gives an infinite series of harmonics with every 4th one (4th, 8th, 12th, etc.) equal to zero. The values of the first ten harmonics in per cent of the steam loading F , are given in Table 2. Even the 30th harmonic has an amplitude of 2

TABLE 2 VALUES OF FIRST TEN HARMONICS

No. of harmonic	Intensity, per cent
1	45.0
2	31.8
3	15.0
4	0
5	9.0
6	10.6
7	6.4
8	0
9	5.0
10	6.4

per cent, which is sufficient to set up a vibration of considerable magnitude. This gives some indication of why impulse excitation can be so destructive. Further troublesome characteristics of impulse excitation will be brought out in the next section.

TUNING OF TURBINE BLADES

Whenever the frequency of one of the various harmonics of the exciting force coincides with a natural frequency of the blade, resonance will occur. As explained earlier, the vibration amplitude will be equal to the static deflection produced by the component, multiplied by the magnification factor. Assume, for instance, that a blade is subjected to a steady steam force of 6 lb plus a certain harmonic whose magnitude is 5 per cent. The harmonic force will then have an amplitude of 0.3 lb. The static deflection is then considered to be the deflection which would be produced by a force of 0.3 lb uniformly distributed over the blade. If the magnification factor is 200, the deflection at resonance would correspond to that produced by a force of 60 lb. The resultant vibratory stress also would be equal to that produced by a 60-lb load, and would thus be 10 times the stress produced by the total steam load which acts statically on the blade. Such bending stresses when superposed on the already high centrifugal stresses may cause fatigue failure if the turbine runs for long periods at a resonant condition.

As already mentioned, experience with turbines indicates that the lower harmonics usually have the largest amplitudes. There have been many failures which were caused by the 4th or lower harmonics. There also have been some failures at higher-order harmonics. It is therefore necessary to avoid resonance at the 4th and lower harmonics or, when it cannot be avoided, have it occur at a reduced speed where the centrifugal stress acting on the blade will be less than at full power.

A convenient means of visualizing this problem is the Campbell diagram, named for the late Wilfred Campbell of the General

Electric Company, who did much of the pioneer work on turbine vibration. The Campbell diagram is shown in Fig. 7. It consists of a series of curves of frequency (usually cycles per minute) plotted versus turbine revolutions per minute. On this diagram each harmonic is represented by a straight line passing through the origin. These lines give the frequencies of the exciting forces corresponding to the various harmonics, at all speeds of the turbine. The second harmonic will have twice the slope of the first, the third harmonic three times, etc. Usually, about eight harmonics are drawn.

After the frequencies of all of the important exciting forces have been plotted on the Campbell diagram, the natural frequencies of the blading are plotted. When the turbine is not rotating, the natural frequency of a blade (or group of blades joined by a shroud band), has a particular value which is called the static frequency. When the turbine is running, the centrifugal force has a stiffening effect on the blade, raising its natural frequency. This is the running frequency. These frequencies also can be plotted on the Campbell diagram. The curves for two stages, A and B, are shown in Fig. 7. The running frequency is fairly close to static frequency up to about half speed of the turbine. Above this speed the frequency increases appreciably. At maximum speed the increase in frequency is usually around 15 per cent for the longest blades.

FIG. 7 CAMPBELL DIAGRAM

With the blade frequencies added, the Campbell diagram is complete. Each point at which the blade-frequency curve crosses one of the harmonics, represents a condition of resonance. There are thus numerous resonant conditions for each blade. Most of them are excited by high-order harmonics and are therefore not serious. The lowest order of resonance is the one of which to beware, because it occurs at the highest turbine speed and probably will have the largest exciting force.

Turning now to the curve for blade A, in Fig. 7, it can be seen that at maximum speed, resonance does not occur, and the blade frequency lies halfway between the 3rd and 4th harmonics. If the natural frequency of 13,500 is divided by the turbine rpm of 3850, the result is 3.5. This is usually called 3.5 vibrations per revolution. This value is not a coincidence. As originally laid out, this blade had 4.1 vibrations per revolution, which was very close to a dangerous resonant condition. It was not considered practical to stiffen the blade sufficiently to raise it to 4.5 vibrations per revolution, so, the blade section was reduced in order to lower the frequency to 3.5 vibrations per revolution. This process is called tuning. It is a fairly lengthy design process involving considerable work.

Referring back to the Campbell diagram, it will be seen that at 3300 rpm, stage A is in resonance with the 4th harmonic. At this condition, however, the steam load on the blade is less than at full power (probably down to 70 per cent of the full-power value) and

therefore the magnitude of the exciting force is reduced proportionately. In addition to this, the centrifugal stress in the blade is down to 12,200 psi, instead of the 16,600 psi which it had at full power. The total steam load on this blade at full power is 6.5 lb per blade, producing a steam bending stress of 550 psi. At 3300 rpm the bending stress may be assumed to be about 390 psi, (70 per cent of 550). If this steam force contained a 4th harmonic with a magnitude of 5 per cent of the steady steam force, and the vibration magnification factor were 200, the vibratory stress would be $390 \times 0.05 \times 200 = 3900$ psi.

A comparison of the blade stresses at full speed (3850 rpm) and at 3300 rpm, is given in Table 3.

TABLE 3 BLADE STRESSES AT 3850 AND AT 3300 RPM (STAGE A)

(a) Rpm.....	3300	3850
(b) Centrifugal stress, psi.....	12200	16600
(c) Static steam stress, psi.....	390	550
(d) Total steady stress (b + c), psi.....	12590	17150
(e) Vibratory stress, psi.....	3900	negligible
(f) Maximum stress (d + e), psi.....	16490	17150
(g) Minimum stress (d - e), psi.....	8690	17150

Thus it can be seen that although 4th-order resonance has not been avoided, it has been located at a speed where less severe stresses are encountered. Had 4th-order resonance occurred at full speed, the steady stresses would be 17,150 psi, and the vibratory stresses 5500 psi, leading to a maximum stress of 22,650 psi, and a minimum stress of 11,650 psi.

Stage B has been handled in a similar manner except that it is tuned to have the full-power condition fall between the 5th and 6th harmonics. Unless a blade is very highly stressed, it does not appear necessary to tune for harmonics above the 6th. Assuming the vibratory stress at resonance in stage B to be 10 times the steam bending stress, it will compare with stage A, as in Table 4.

TABLE 4 COMPARISON OF STRESSES IN STAGES A AND B

Stage	Resonant rpm	Harmonic	Centrifugal stress, psi	Steam bending stress, psi	Total steady stress, psi	Vibratory stress, psi
A	3300	4	12200	390	12590	3900
B	3550	6	12500	510	13010	5100

Although the stress in stage B is higher than that in stage A, when calculated by this arbitrary method, it should be remembered that the exciting force of the 6th harmonic will be much less than the 4th, and the factor of 10 is therefore rather severe.

It is in connection with tuning that one of the most objectionable features of impulse excitation becomes apparent. First-stage blades, which are subjected to impulse excitation, have high natural frequencies which ordinarily would put them well out of reach of vibration trouble. Their frequencies may be 25 or more vibrations per revolution. It was, however, mentioned in the preceding section, that even the 30th harmonic of impulse excitation may have an exciting force of 2 per cent. Thus these blades will be subjected to sizable exciting forces. Even assuming that it were possible to tune a blade accurately enough to obtain 24.5 vibrations per revolution, it would be in resonance at 25 vibrations per revolution when the speed dropped 2 per cent. This change is no more than that which would be encountered in going from light draft to load draft, or from clean bottom to foul bottom. It is thus impossible to avoid resonance at, or very close to, maximum speed. Therefore the blades must be designed to withstand such conditions. This can be done by keeping low bending stress and using materials which have good damping properties at the operating temperatures. Thirteen per cent chromium stainless steel has relatively good damping properties.

In the process of tuning, there are several ways of changing the frequency, and usually two or more of them are used together. In discussing the methods it would be well to consider the equa-

tion for the frequency of a cantilever beam of constant section, which shows the effect of several of the factors which determine blade frequency. This equation is

$$F_s = 660 \sqrt{\frac{EI}{Wl^4}} = \sqrt{\frac{EI}{\rho A l^4}}$$

where

F_s = static frequency, cycles per min (cpm)

E = modulus of elasticity, psi

I = moment of inertia of cross section, in.⁴

l = length of beam (length of blade), in.

ρ = density of material, lb per cu in.

A = area of cross section, sq in.

W = weight per in. of beam = ρA , lb per in.

In this equation, E and ρ may be considered fixed, since the material is usually settled in advance. That leaves the possibility of altering A , I , and l . Increasing the value of I , will increase the frequency. If a small increase is desired, it can be accomplished by thickening the blade slightly. If a large increase is needed, the necessary thickening would restrict the steam passage too much. In this case the entire blade section may be increased, maintaining the same geometric proportions. Either process increases the area A simultaneously. Moment of inertia, however, increases as the 4th power of the linear dimensions, while A increases as the 2nd. Thus frequency will increase about in proportion to the increase in lateral dimensions.

Another method of changing frequency is to change l . Since frequency varies as l^2 , this method is effective. It is usually an increase in frequency which is desired and, in this case, l would be decreased. This, however, may be a costly process because it will lower the efficiency of the stage. Therefore height decreases are used rather sparingly.

The third method of altering frequency is to taper the blade, or alter the taper on one which already has it. Tapering a blade not only increases the blade frequency, but it is most effective in reducing centrifugal stress. If the stage A in Fig. 7 were made with constant cross section (using the base section), its static frequency would be about 13 per cent lower, and the centrifugal stress 70 per cent higher. Tapered blades are also "twisted" frequently. This is done to suit the angle of the incoming steam.

Shroud bands and lacing wires affect the frequency. Shroud bands do not necessarily raise the frequency. They do stiffen the blades, but the added mass sometimes counteracts the added stiffness. In some cases, however, shroud-band alterations can be used as an aid in tuning. Lacing wires increase the frequency, particularly when there are two rows of them. Altering their size will alter the frequency.

Application of any of these methods of tuning usually is limited by the action of some other factor such as loss of thermodynamic efficiency, increase in stress, or difficulty of manufacture. It is for this reason that several methods may be applied simultaneously to obtain the desired result.

The subject of tuning cannot be dismissed without some mention of the calculating methods which must be applied with every change. Only the briefest discussion of them can be given in this paper because a detailed treatment would result in the writing of a textbook.

The calculation of a tapered twisted blade is a tedious process. It is necessary first to calculate maximum and minimum moments

of inertia and weight per inch of blade at several sections (usually at least three sections are taken and a curve is drawn through the three points thus obtained). For the actual frequency calculation, the Rayleigh method is frequently used. In this method, the potential and kinetic energy must be calculated for a given assumed deflection curve. Ordinarily, the static-deflection curve, obtained by loading the blade with its own weight, is taken as the assumed curve. In this case, the calculation is represented by the equation

$$F_s = 188 \sqrt{\frac{\int w y d l}{\int w y^2 d l}}$$

where

w = weight per unit length of blade
 y = ordinate of deflection curve
 $d l$ = differential length

If the assumed curve is reasonably close to the shape of the actual vibration curve, a good approximation is obtained. In using the static-deflection curve, the error seldom exceeds 2 per cent. If greater accuracy is required, it is necessary to make a second approximation, based upon the first calculation.

Twisted blades present a problem because the axes of the cross sections do not lie in one plane. This requires using two reference planes at right angles and working with co-ordinates. An expedient which has been used to avoid this, is to work two approximate calculations. In the first, the minimum moments of inertia for all sections are rotated into a single plane and the frequency calculated. This gives a frequency which is too low. The other calculation uses the moment of inertia, of each section, about an axis parallel to the minimum axis of the base section. This gives a frequency which is too high. By interpolating between these two frequencies and using factors obtained from tests, it is possible to obtain frequencies which are close enough for preliminary design work.

Final blade-frequency calculations involve the effect of the shroud band or lacing wires. In this case the structure is indeterminate and requires the application of strain-energy methods.

Finally, it is necessary to calculate the effect of centrifugal force. For blades of constant cross section, Campbell used the formula

$$F_r = \sqrt{F_s^2 + B N^2}$$

$$B = 1.56 \times \frac{R}{l} + 1.17$$

where

F_s = static frequency
 F_r = running frequency
 l = blade length
 R = radius to base of blade
 N = rpm of turbine

This formula may also be used for preliminary calculations on tapered blades. For final calculations, it is necessary to calculate the radial shortening caused by the lateral bending of the blade, and then calculate the potential energy which is stored up by producing this radial shortening against the action of centrifugal forces. The effect of centrifugal force on the vibration of a turbine blade is analogous in some ways, to the effect of gravity on the frequency of a pendulum.

BLADE TESTING

Consideration of the Campbell diagram shows that an error of a few per cent in the calculation of blade frequency could lead to

disaster. Therefore it is natural that testing should be an important phase of blade design. In this way the various factors affecting frequency can be determined, and empirical design coefficients chosen. For this purpose a vibrator can be used to determine the natural frequencies of blading. The vibrator, illustrated in Fig. 8, was built from a loud-speaker. The cone was sawed off and a small threaded nut cemented to the moving ele-

FIG. 8 VIBRATOR FOR DETERMINING NATURAL FREQUENCIES OF TURBINE BLADES

ment. One end of a small aluminum rod ($\frac{3}{32}$ in. diam) is screwed into this nut, and the other end is attached to the blade by means of a spring clip. The permanent-magnet field of the speaker has been replaced by an electromagnet of considerably greater field strength. By supplying an alternating current to the coil of the speaker, a corresponding alternating force of about 0.5 lb peak value can be obtained. A Hewlett-Packard 200-B, 1-watt oscillator is used for this purpose, and it supplies sufficient power to vibrate most turbine blades. The oscillator frequency is varied until resonance occurs, and the frequency can be read on the oscillator dial. By using a micrometer drive for the dial and calibrating with a cathode-ray oscillograph, very high precision can be obtained when needed.

Single blades to be tested are clamped to a heavy metal slab, usually using filler blocks which cover the root and packing piece. When testing an entire group of blades, complete with shroud band, the blades are mounted in a grooved block which simulates a section of the turbine rotor. Such a group can be seen in Fig. 8.

Another type of testing which is necessary in blade designing is the combined tensile and fatigue test. In this test a tensile load is applied to the blade to simulate centrifugal force. At the same time, vibratory stresses are simulated by the application of a lateral alternating force. A machine for making such tests is shown in Fig. 9. A beam, weight-loaded at the end, applies the tensile load (up to 21,000 lb). A connecting rod, attached to an adjustable eccentric, applies a bending deflection to the blade. The eccentric is driven by a motor with a speed range of 1000 to 2200 rpm. The bending stress in the blade is checked by means of bonded resistance-wire (SR-4) strain gages. This machine is used to determine the fatigue strength of blading, and also for comparative tests of modifications to blade roots. It was used in

FIG. 9 MACHINE FOR MAKING COMBINED TENSILE AND FATIGUE TESTS

FIG. 10 FATIGUE TEST OF 2-IN. TURBINE BLADE

arriving at the size of fillet to be used in the roots of the stages, A and B, which were shown in Fig. 7.

In making combined tensile and fatigue tests, a certain tensile load is applied, and then a series of tests are run at different bending stresses. Each test is continued until the specimen either breaks or withstands 10,000,000 stress cycles. A curve of bending stress versus number of cycles is then plotted. Such a curve is shown in Fig. 10. It will be noticed that the curve falls rapidly at first and then levels off. At 10,000,000 cycles the curve is practically flat. With ferrous materials, it is assumed that a specimen which withstands 10,000,000 stress cycles will last indefinitely. In this paper the ordinate of the curve at 10,000,000 cycles will be called the endurance limit. This term must be used with caution because endurance limit is usually used to indicate the fatigue strength of the material subjected to alternating stress only. In this case there is a combination of steady stress and alternating stress. A separate endurance limit can be obtained for each value of steady stress.

The several values of endurance limit may be plotted on a curve such as that shown in Fig. 11. Here, endurance limit is plotted as the ordinate and steady stress as the abscissa. In the plot shown in Fig. 11 there are only two points. The tests were all run with 30,600 psi steady stress, which gave one of the points. The other point is the steady stress corresponding to zero alternating stress. This is simply the tensile strength of the material.

FIG. 11 FATIGUE-STRENGTH DIAGRAM FOR 2-IN. TURBINE BLADE

These have been joined by a straight line. Published literature on the subject indicates that this is a reasonable assumption to use when intermediate points are lacking. The resulting curve shows the strength of a particular blade for any combination of steady and vibratory stress. However, the curve should be representative of other blades of similar design.

FACTOR OF SAFETY

In most stress problems it is desirable to calculate a factor of safety. In turbine-blade vibration there is much that is not known and that is why designers prefer statistical methods aided by comparative stress and vibration calculations. The magnitudes of both exciting and damping forces are in considerable doubt. One manufacturer multiplies the steady steam bending stress by 10, adds it to the centrifugal stress at full power and considers that the working stress for the blade. This appears to be a reasonably rational approach when it is considered that it is equivalent to a harmonic exciting component of 5 per cent of the steady steam force, and an amplification factor of 180. The 5 per cent factor appears quite conservative in the light of the few measurements of variations in steam force which are available (except in the case of impulse excitation). In fact, it is difficult to see how this figure could be approached in a carefully designed turbine, unless there were some damage to blading or nozzles.

The amplification of 180 also appears reasonable for 13 per cent chromium stainless-iron blading in a low-pressure turbine. The 5 per cent exciting force and amplification of 200 which have been assumed several times in this paper are very nearly identical with it. What this method does appear to need is an additional factor whereby the decreasing intensity of higher harmonics could be considered.

Returning now to Fig. 11, we can plot the stresses for stage A from Table 3 of a previous section. The bending stress required for failure at the given static stress of 12,590 psi, is 44,000 psi, giving a factor of safety of $44,000 \div 3900 = 11.3$. At first glance this might seem to be an excessively high factor of safety. It is conservative, but turbine blades are subject to corrosion fatigue. Metals subjected to alternating stresses in an atmosphere of steam or water, have much lower endurance limits than in air. Because of this it would be reasonable to divide the foregoing factor of safety by 2, thus obtaining 5.6.

Four failures have been plotted in Fig. 11. The blades involved had the characteristics given in Table 5.

In each case the bending stresses have been multiplied by 10 before plotting in Fig. 11. Blades X and Y-1 both failed after several years of service. Both were in the last row of the high-pressure turbine, where they were subjected to relatively large variations in heat drop around the periphery. Since both had approximately 12 vibrations per revolution, they would not ordi-

TABLE 5 CHARACTERISTICS OF BLADES WHICH FAILED

Manufacturer	Turbine	Cent. stress, psi	Steam bending stress, psi	Total static stress, psi	Vibrations per rev	Failure
X	HP	6410	3610	10020*	11.9	Blade
Y (case 1)	HP	5000	3390	8390	12.5	Blade
Y (case 2)	LP	19800	1590	21390	4.0	Shroud
Z	LP	11200	700	11900	4.2	Root

narily be expected to give trouble. The bending stresses were, however, so high that even with the small excitation obtained from the 12th harmonic they succumbed to corrosion fatigue. In considering these stresses, it must be remembered that the factor of 10 is excessive for the high-order vibration. The remedy for such blade trouble is to lower the bending stress by using a heavier blade section.

With blade Y-2, 4th-order resonance was encountered at full power. The blade itself did not fail but the vibration was sufficiently severe to crack the shroud band. Broken shroud bands are liable to jam and tear up the blading. In the case of blade Z, failure was attributed to axial vibration of the wheel. However, exact diagnosis of blade failure is usually difficult, and the prox-

imity to 4th-order resonance appears suspicious.

In connection with design, it should be emphasized that great care must be exercised in proportioning all fillets on turbine blading. A sharp re-entrant corner at the base of the blade, or in the root can be the starting point for a fatigue crack which will cause the failure of an otherwise successful blade.

CONCLUSION

From the foregoing illustrations and discussion, it can be seen that the design of blading to resist vibration is far from an exact science. In spite of this, high efficiencies are being obtained, while blade failures from fatigue have been reduced to a point where they are considerably less than failures from other causes.

Theory of the Mechanical Properties of Hot Plastics

By S. J. LORING,¹ EASTON, CONN.

This paper describes a theory of large strain, rubber-like elasticity combined with stress relaxation, which is the character of the behavior of hot plastics indicated by a series of unpublished high extension rate tests on such materials as polystyrene, polyethylene, acetate, etc., in the molten or "soft" state.

NOMENCLATURE

a_{ij} = natural strain components
 A_{ij} = auxiliary strain quantities defined in terms of a_{ij}
 C = pressure gradient in channel or tube flow
 D = "diffusion coefficient" representing effect of thermal agitation of molecules on their phase-space co-ordinates
 f = representative molecular force
 $f(x_1)$ = designation for arbitrary function in channel- and tube-flow analysis
 f_{11}, f_{22} = functions representing stresses due only to elastic strain in channel and tube flows
 F_{22} = function representing stress due only to elastic strain in tube flows
 F_1, F_2, F_3 = forces on sides of parallelepiped of material
 G = modulus of rigidity entering specific strain-energy functions
 h = semiheight of channel or radius of tube
 H, H' = auxiliary parameters in analysis of channel and tube flows
 i, j, k = "dummy" indexes ranging over values 1, 2, 3
 K = constant of proportionality between representative molecular force f and length r
 l_{ij} = direction cosines relating directions of x_1, x_2, x_3 and y_1, y_2, y_3 axes
 L_1, L_2, L_3 = fixed reference lengths
 m_{ij} = direction cosines relating directions of x_1, x_2, x_3 and z_1, z_2, z_3 axes
 M_{ij} = auxiliary strain quantities defined in terms of a_{ij} and m_{ij}
 n = exponent in specific relaxation and strain-energy functions
 N = number of molecules per unit volume
 p = hydrostatic tension independent of elastic strain in incompressible materials
 p_0 = constant hydrostatic tension in channel or tube-flow analysis
 q = volume rate of flow per unit width in channel
 Q = volume rate of flow in tube
 r = representative length of chain molecule
 r_0 = reference value of r
 R_1, R_2, R_3 = functions describing relaxation process
 s = shearing rate in simple shear
 S = dimensionless measure of shearing rate s

t = time
 T = "relaxation time" entering specific relaxation functions
 v_0 = constant of integration in flow-velocity integrals for channel or tube
 v_1, v_2, v_3 = flow-velocity components in x_1, x_2, x_3 directions
 v_r = "drift" velocity of phase-space co-ordinates of a molecule due to molecular force
 W = work done on unit volume of material by external forces
 x_1, x_2, x_3 = fixed direction Cartesian co-ordinates; in dealing with strain a single prime (') denotes position of point in unstrained condition, and double prime (") in strained condition
 X, X' = auxiliary parameters in analysis of channel or tube flows
 x, y, z = Cartesian co-ordinates in phase space
 y_1, y_2, y_3 = Cartesian co-ordinates with same origin as x_1, x_2, x_3 but directed along lines in unstrained condition which become principal axes in strained condition. Single and double primes ('), (") have same significance as for x_1, x_2, x_3
 z_1, z_2, z_3 = Cartesian co-ordinates with same origin as x_1, x_2, x_3 but directed along lines of principal strain in strained condition. Single and double primes ('), (") have same significance as for x_1, x_2, x_3
 $\alpha_1, \alpha_2, \alpha_3$ = principal extension-strain ratios—referring to elastic strain in Sections 3, 4, and 5
 η = viscosity coefficient for Newtonian liquid
 η_c = apparent viscosity for flow in channel
 η_s = apparent viscosity for simple shear flow
 η_t = apparent viscosity for flow in tube
 θ = angle between principal strain axis z_1 and axis x_1 in two-dimensional strain
 θ_1 = angle between unrotated principal axis y_1 and axis x_1 in two-dimensional strain
 $\lambda_1, \lambda_2, \lambda_3$ = parameters in linear relations between M_{ij} and m_{ij}
 μ = assumed constant of proportionality between v_r and molecular force f
 ρ = distribution function in phase space
 ρ_0 = equilibrium distribution function
 $\sigma_1, \sigma_2, \sigma_3$ = principal stresses
 σ_{11}, σ_{22} = tension stresses on x_1, x_2 co-ordinate plane
 τ = shear stress on x_1, x_2 co-ordinate planes
 Φ, Φ' = auxiliary functions for channel flow
 ψ = strain-energy function

1 INTRODUCTION

The mechanical stress-flow properties of hot plastics are of considerable practical importance in the study of various plastic-manufacturing processes, such as extruding, molding, injection molding, etc. The results of a series of tension tests on several hot plastic materials, which are reported by the author,² indi-

² "Report on Tensile Tests on Hot Plastics at High Extension Rates"; report prepared for Plax Corporation by S. J. Loring, December, 1948.

¹ Consulting Engineer. Mem. ASME. Contributed by the Rubber and Plastics Division and presented at the Annual Meeting, New York, N. Y., November 27–December 2, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49—A-60.

cate that the flow properties of these materials result from a rubberlike large deflection elasticity combined with a stress relaxation property.

The elastic and relaxation properties combine to produce flow characteristics which are in many ways similar to those of the classical Maxwell liquid. The classical Maxwell liquid theory, however, implies that the elastic strains are of infinitesimal, or at least very small magnitude as is also assumed in the classical theory of elasticity. In contrast, the subject materials exhibit very large elastic strains, with extension ratios of the order of 2 or even 10, and these large elastic strains have profound effects upon the behavior of the materials as compared to the classical Maxwell liquid.

The important novel effects introduced by large elastic strain as opposed to small strain originate from two principal sources. One source of novel effects lies in the geometrical properties of large strain itself, which are considerably more complex than those of small or infinitesimal strain. The other source of new complexities is the fact that both the elastic and relaxation rates are affected by the changes in internal structural arrangement of the materials which must accompany large strain; these rates no longer can be considered linear as in classical theories.

A theory of the mechanical behavior of materials exhibiting large-strain elasticity and stress relaxation is developed in the present paper, in which consideration is given both to the geometrical properties of large strain and to the nonlinearity of elasticity and relaxation which accompany large strain.

The theory is based upon the mathematical treatment of large strain presented in Section 2. This treatment differs from most other treatments of large strain in that it is developed from the specification of the state of strain at the individual points of a body rather than a general specification of the state of distortion of the body as a whole. The strain at the individual points is then related differentially to the distortion of the body as a whole by specifying its time rate of change in terms of flow velocities. This point of view appears simpler than the usual one because the current strain condition can be followed during the course of a deformation without the complexities and ambiguities that arise in relating the positions of points in the body directly to their original or unstrained positions. The viewpoint is, in addition, particularly well adapted to the treatment of the relaxation process in flows, which leads to real ambiguities with the older method.³

In Section 3 the mathematical specification of general elastic and relaxation properties is developed from a phenomenological and macroscopic point of view. It is pointed out at the end of that section that numerical implementation of this specification requires data relating to the internal structure of the materials.

A simple molecular representation of internal structure is set up in Section 4, and analyzed by the methods of statistical mechanics to illustrate the structural significance of the phenomenological concepts introduced to describe the macroscopic mechanical behavior. This analysis leads to definite mathematical functions which describe the elasticity and relaxation of the simplified representation, and which may be used as starting points for interpretation of test data on actual materials.

General solutions for the steady-state flows in channels and tubes are developed in Section 5, and their numerical application is illustrated by carrying out numerical computations with strain-energy and relaxation functions which are in accord with the tensile test data of the author.³ Comparison is made with some test data on flows through channels and tubes, and the agreement with the theory is encouraging.

Regarding extensions in the applications of this theory, it is interesting to note that the principal novel concepts in large elastic strain are very similar to those described by Bailey⁴ as orientation in cold plastics. It appears that the understanding of the mechanical properties of hot plastics may be extended and lead to understanding of the more complex properties of cold plastics.

In any event, it is hoped that the theory in its present form will serve as a basis for interpretation of observations on the mechanical behavior of hot plastics, and when fully implemented by such observations, will serve as a basis for rational and quantitative treatment of some of the flow problems involved in the manufacture of plastic articles.

2 GEOMETRY OF LARGE STRAINS

(a) *The Notion of Strain.* Since the properties of large strain differ in a number of ways from those of the small strain of classical theory, some of the commonly accepted attributes of small strain must be discarded in treating large strain. For this reason the developments of this section are introduced by an account of the general notion of strain of unrestricted magnitude. This account is directed to the viewpoint to be adopted in the following treatment of large strain.

A complete and detailed description of circumstances in which the relative positions of the points of a body change requires the notion of strain. Consideration of those circumstances will serve to bring out the basic concepts involved in the notion of strain.

Note first that change in the relative positions of the points of a body implies a comparison of two states of deformation of the body. Therefore two distinct configurations of the points of a body must be involved in the notion of strain; specifically, the comparison of the two configurations is involved.

Changes in relative position of distant points of the body result from vectorial addition of the changes of relative position of a number of closer intermediate points, and they are, therefore, implied by the latter changes. The closer the points of the body that are individually identified the more complete the description of the relative state of distortion in the two configurations.

In the limit, a complete description of a distortion of a body can consist of a catalog of the relative position changes of all its pairs of points which lie an infinitesimal distance apart. Such a catalog may be conceived as being composed of sections each of which is devoted to a particular point and contains the information for all pairs of points separated by an infinitesimal distance and of which the particular point is a member. Multiple listings required for this arrangement of the catalog will, of course, not affect its completeness, which is all that matters for the present purposes.

The information contained in that section of the catalog described in the preceding paragraph which is devoted to a particular point is just the information which is contained in a specification of the state of strain at the point. The mechanics of this specification, and its properties, form the subject matter of the present treatment.

Most classical treatments of strain are restricted to the case of "small" strains, in which case the changes in the distances between pairs of neighboring points are very small compared to these distances themselves. This restriction is inappropriate for the present purposes and is completely abandoned. In the treatment which follows no assumption is made as to the magnitude of the changes which take place in the distances between

³ See, for example, footnote, and discussion just prior to that reference.

⁴ "Stretch Orientation of Styrene and Its Interesting Results," by James Bailey, *India Rubber World*, vol. 118, May, 1948, pp. 225-231.

neighboring points, except that they are continuous from point to point and remain finite.

(b) *Specification of Strain at a Point.* In order to specify the strain at a point in a body, a set of Cartesian co-ordinates x_1, x_2, x_3 is set up with the origin at the point in question. The directions of these axes remain fixed, but the origin stays on the point of the body and moves with it during a deformation.

Let the x_1, x_2, x_3 -co-ordinates of any neighboring point be designated by x_1', x_2', x_3' "before the deformation," and let them be designated by x_1'', x_2'', x_3'' "after the deformation." Specification of the strain at the point consists of a general expression for x_1'', x_2'', x_3'' in terms of x_1', x_2', x_3' in which, however, these co-ordinates are limited to infinitesimal values.

Any relationship between x_1'', x_2'', x_3'' and x_1', x_2', x_3' can be expressed as power series in x_1', x_2', x_3' . The constant term in the series for each of x_1'', x_2'', x_3'' is zero since, by definition, the reference axes move with the reference point in the body, that is, $x_1' = x_1'' = x_3' = 0$ always implies that $x_1'' = x_2'' = x_3'' = 0$. Furthermore, since x_1', x_2', x_3' are limited to infinitesimal values, powers above the first may be neglected in the series. Accordingly, the most general expression for strain at a point is

$$\left. \begin{aligned} x_1'' &= a_{11}x_1' + a_{12}x_2' + a_{13}x_3' \\ x_2'' &= a_{21}x_1' + a_{22}x_2' + a_{23}x_3' \\ x_3'' &= a_{31}x_1' + a_{32}x_2' + a_{33}x_3' \end{aligned} \right\} \dots\dots\dots [1]$$

The strain is specified by the nine quantities $a_{11} \dots a_{33}$ which will be called the natural strain components. Though they are in a different form, the natural strain components are equivalent to the strain components usually employed in the classical theory of elasticity. However, as remarked before, in this work no assumption is made as to the magnitudes of the strain components except that they remain finite.

In the exposition which follows a number of equations will be encountered which, like Equations [1], have groups of similar terms in which only the indexes change. It will be convenient to shorten the writing out of these equations by use of the standard summation symbol Σ , and the letter indexes i, j, k , which range over the values 1, 2, and 3. The index to which the summation refers will be indicated by placing this index under the summation sign, and the ranges of other indexes will be indicated in parentheses after each expression. Thus Equations [1] can be written

$$x_i'' = \sum_j a_{ij}x_j', \text{ (for } i = 1, 2, 3) \dots\dots\dots [1a]$$

(c) *Resolution of Strain Into Three Principal Strains and a Rotation.* For treatment of the generalized types of elasticity and relaxation to be discussed in the sequel it is convenient to reduce the specification of a strain to a standard and uniquely simple form rather than to use the natural strain components of Equations [1].

It will be shown that any strain specified by Equations [1] is equivalent to, and can be resolved into three simple extensions along three suitably directed mutually perpendicular axes, plus a rigid-body rotation. The three simple extensions of this resolution are called the principal strains. Thus, according to this resolution, there are only three really independent components of strain proper; in addition to these three principal strains, the natural strain components a_{ij} also specify the orientation of the principal axes of strain and a rigid-body rotation. The resolution into principal strains will isolate these three aspects of a general strain given by Equations [1].

To effect this resolution introduce two additional sets of Cartesian co-ordinates with origins also staying on the point of the body which is the origin of the x_1, x_2, x_3 axes. These new co-ordinates are designated y_1, y_2, y_3 and z_1, z_2, z_3 ; their axes differ

from x_1, x_2, x_3 only in orientation, and expressions relating the co-ordinates themselves to x_1, x_2, x_3 are

$$y_i = \sum_j l_{ij}x_j, \text{ (for } i = 1, 2, 3) \dots\dots\dots [2]$$

and

$$z_i = \sum_j m_{ij}x_j, \text{ (for } i = 1, 2, 3) \dots\dots\dots [3]$$

In these relations l_{ij} and m_{ij} (for $i, j = 1, 2, 3$) are, respectively, sets of direction cosines relating two sets of orthogonal axes. They each satisfy the well-known identities for such direction cosines which express the orthogonality of the two sets of axes. These identities are used in subsequent derivations and will be written here for the m_{ij} for reference purposes

$$\sum_j m_{ij}^2 = 1, \text{ (for } i = 1, 2, 3) \dots\dots\dots [4]$$

$$\sum_j m_{ij}m_{kj} = 0, \text{ (for } i \neq k, \text{ and } i, k = 1, 2, 3) \dots\dots\dots [5]$$

It may be noted that Equations [5] comprise only three equations since for these equations i is specified to be not equal to k , and interchange of i and k does not change the terms of the summation. The terms that would result from $i = k$ in Equation [5] are the terms of Equations [4]. From the identities, Equations [4] and [5], the following similar identities can be derived

$$\sum_i m_{ij}^2 = 1, \text{ (for } j = 1, 2, 3) \dots\dots\dots [4a]$$

$$\sum_i m_{ij}m_{ik} = 0, \text{ (for } j \neq k, \text{ and } j, k = 1, 2, 3) \dots\dots\dots [5a]$$

Observations can be made concerning the identities, Equations [4a] and [5a], which are entirely similar to those already made concerning Equations [4] and [5].

Similar identities hold, of course, for the l_{ij} .

In a fashion similar to that already specified for x_1, x_2, x_3 , the single prime (') is used to designate the y - and z -co-ordinates of points in the body before deformation, and the double prime (") after deformation.

For each given strain, the orientation of the y - and z -axes, that is, l_{ij} and m_{ij} , are set as follows: The z_1, z_2, z_3 co-ordinate axes are directed along the three principal strain axes in the deformed body. The points of the body in the neighborhood of the reference point which lie on these principal strain axes after deformation will have lain along three mutually perpendicular straight lines before the deformation took place; these lines, however, generally have different directions than the principal strain axes in the deformed state, because of the rigid-body rotation component of the strain. The y_1, y_2, y_3 axes are directed along the three mutually perpendicular lines thus defined. It is seen then that the orientation of the z -axes, i.e., the m_{ij} , locates the principal axes of strain in the deformed body; and also that the difference in orientation between the z -axes and the y -axes, i.e., the m_{ij} and the l_{ij} , determine the rigid-body rotation part of the strain.

Let the three principal extension "strain ratios" be designated by α_1, α_2 , and α_3 . The strain expressed by Equations [1] is, then, asserted to be equivalent to a strain specified by

$$\left. \begin{aligned} z_1'' &= \alpha_1 y_1' \\ z_2'' &= \alpha_2 y_2' \\ z_3'' &= \alpha_3 y_3' \end{aligned} \right\} \dots\dots\dots [6]$$

or

$$z_i'' = \alpha_i y_i', \text{ (for } i = 1, 2, 3) \dots\dots\dots [6a]$$

The problem at hand is to show that a strain given by Equations [6] can be made to coincide with any given by Equations [1], by

suitable choices of the principal strain ratios α_i and of the direction cosines m_{ij} and l_{ij} ; and further to determine the α_i , m_{ij} , and l_{ij} in terms of the natural strain components a_{ij} of Equations [1]. The balance of this subsection is devoted to this problem.

Use the relations of Equations [2] and [3] to express Equations [6] in terms of the x_1, x_2, x_3 co-ordinates; thus

$$\sum_j m_{ij} x_j'' = \alpha_i \sum_j l_{ij} x_j', \quad (\text{for } i = 1, 2, 3) \dots \dots \dots [7]$$

Now, solve these three equations for x_1'', x_2'', x_3'' , respectively, by multiplying the respective equations first by m_{i1} and adding, then by m_{i2} and adding, and finally by m_{i3} and adding. This process solves the equations for x_1'', x_2'', x_3'' by virtue of the identities, Equation [4a] and [5a]. The coefficients of the x_j' in the resulting equations solved for the x_i'' , by comparison with Equations [1], are seen to be equal to the natural strain components a_{ij} . Thus

$$a_{ij} = \sum_k \alpha_k l_{kj} m_{ki}, \quad (\text{for } i, j = 1, 2, 3) \dots \dots \dots [8]$$

There is a total of nine separate equations in Equations [8], one for each of the nine a_{ij} .

In order to obtain explicit equations for the direction cosines m_{ij} , start by forming the following nine equations from Equations [8], with the help of the identities, Equations [4] and [5].

$$\sum_i a_{ij} m_{ki} = \alpha_k l_{kj}, \quad (\text{for } k, j = 1, 2, 3) \dots \dots \dots [9]$$

In these equations the m_{ij} occur only in the left-hand sides, while the l_{ij} occur only on the right. Now, with the help of the identities of the type of Equations [5] in the direction cosines l_{ij} , the three combinations:

$$\alpha_i \alpha_k \sum_j l_{ij} l_{kj} = 0, \quad (\text{for } i \neq k; i, k = 1, 2, 3) \dots \dots [10]$$

of the right-hand sides of Equations [9] may be formed which are identically zero. There are only three distinct relations, Equations [10] since $i \neq k$, and interchange of i and k does not change the relation. The corresponding left-hand sides of the combinations, Equations [10], of [9], which are equal to zero by Equations [10], comprise three equations in the m_{ij} . These three equations in combination with the identities, Equations [4] and [5], serve to determine the values of all the m_{ij} .

The three equations in the m_{ij} are most conveniently written with the help of the following auxiliary notation: Let

$$A_{ij} = A_{ji} = \sum_k \alpha_k a_{ik} a_{jk}, \quad (\text{for } i, j = 1, 2, 3) \dots \dots \dots [11]$$

and further, let

$$M_{ij} = \sum_k A_{kj} m_{ik}, \quad (\text{for } i, j = 1, 2, 3) \dots \dots \dots [12]$$

Note that, if a_{ij} are considered known, the A_{ij} are known constants, while the M_{ij} are "linear combinations" of the m_{ij} with these constants as coefficients. With this notation, the three equations in the m_{ij} may be written as follows

$$\sum_j m_{ij} M_{kj} = 0, \quad (\text{for } i \neq k; i, k = 1, 2, 3) \dots \dots \dots [13]$$

There are only three equations implied by Equations [13] since i is specified to be not equal to k , and the notation of Equations [11] and [12] implies that interchange of i and k does not alter the expanded or intrinsic form of Equations [13].

Comparison of Equations [13] with the identities, Equations [5], shows directly that the m_{ij} and their linear combinations M_{ij} must be connected by the relations

$$M_{ij} = \lambda_i m_{ij}, \quad (\text{for } i, j = 1, 2, 3) \dots \dots \dots [14]$$

where λ_i ($i = 1, 2, 3$) are constants which will be determined.

If the three of Equations [14] with any specific index i are substituted into the three of Equations [12] with the same index i , the following three linear homogeneous equations in m_{i1}, m_{i2}, m_{i3} are obtained

$$\left. \begin{aligned} (A_{11} - \lambda_1) m_{i1} + A_{21} m_{i2} + A_{31} m_{i3} &= 0 \\ A_{12} m_{i1} + (A_{22} - \lambda_1) m_{i2} + A_{32} m_{i3} &= 0 \\ A_{13} m_{i1} + A_{23} m_{i2} + (A_{33} - \lambda_1) m_{i3} &= 0 \end{aligned} \right\} \dots [15]$$

Furthermore, if these equations are to have solutions for the three unknowns m_{i1}, m_{i2}, m_{i3} which are not all zero—which must be the case because of Equations [4]—then the determinant of the coefficients must vanish. Thus

$$\begin{vmatrix} (A_{11} - \lambda_1) & A_{21} & A_{31} \\ A_{12} & (A_{22} - \lambda_1) & A_{32} \\ A_{13} & A_{23} & (A_{33} - \lambda_1) \end{vmatrix} = 0 \dots \dots [16]$$

The numerical values of m_{i1}, m_{i2}, m_{i3} can be obtained for any root λ_i satisfying Equations [16] by use of any two of Equations [15] and condition, Equation [4]. The expanded form of Equations [16] is a cubic equation which has three roots $\lambda_1, \lambda_2, \lambda_3$. These three roots give the values of m_{i1}, m_{i2}, m_{i3} for $i = 1, 2, 3$, respectively. Therefore all the m_{ij} are determined.

The determination of the l_{ij} can be carried out in an entirely similar manner starting with the relations

$$\sum_j a_{ij} l_{kj} = \alpha_k m_{ki}, \quad (\text{for } i, k = 1, 2, 3) \dots \dots \dots [17]$$

In a fashion entirely similar to that for Equations [9], these relations are obtained from Equations [8], with the help of the identities, Equations [4a], [5a]. The determination of the l_{ij} will not be carried out, since the formulas will not be required in the sequel.

Having shown how to determine the numerical values of the direction cosines m_{ij} and l_{ij} , these values may be considered as known. The values of the principal strain ratios α_i can be determined from Equations [9] by forming the three combinations

$$\alpha_i \sum_j l_{ij}^2 = \alpha_i, \quad (\text{for } k = 1, 2, 3) \dots \dots \dots [18]$$

of the right-hand sides. The resulting formulas for α_i are

$$\alpha_i = \sum_{j,k} m_{ij} l_{ik} a_{jk}, \quad (\text{for } i = 1, 2, 3) \dots \dots \dots [19]$$

Here the summation includes a term for each possible combination of j and k for $j, k = 1, 2, 3$. The summation has therefore nine terms, one for each of the a_{jk} .

The resolution of any strain given by Equations [1] into three principal strains in appropriate orthogonal directions and a rigid-body rotation has been effected. The local state of distortion of the material of a body near a point is completely specified by the α_i and the m_{ij} . The only role played by the direction cosines l_{ij} in specifying the strain is in defining the rigid-body rotation in conjunction with the m_{ij} . The rigid-body rotation does not contribute to the local distortion of the material at all, and it will be seen that for a number of purposes, the l_{ij} are extraneous, that is, they do not enter a problem at all. In fact, problems of this type would not have unique solutions in terms of the natural strain components a_{ij} , since the latter contain the extraneous rigid-body rotation.

Problems involving relaxation phenomena are often of this type, since the effect of relaxation on the rigid-body rotational component of the strains is in a sense indeterminate, that is, it depends upon the boundary conditions under which a partially relaxed body is allowed to become elastically restored to zero strain. These boundary conditions are unspecified and really ex-

traneous in problems in which the body is never allowed actually to restore itself to zero strain, for example, in a case of steady-state flow.

The general validity of this resolution is therefore of considerable theoretical significance in treating problems of flow in materials exhibiting relaxation properties. This is the main reason for treating the resolution in the completely general manner of the subsection, i.e., in terms of completely general three-dimensional strain. In the present work actual numerical use of the resolution is made in less general special cases.

(d) *Rate of Change of Strain Components Due to Flow.* The treatment of problems of flow is facilitated by relating the strains at the points of the body to the distortion of the body as a whole through differential relations for the rate of change of the strain components due to flow velocities. Some of these relations will be derived in their general three-dimensional form both in terms of the natural strain components and in terms of the principal strain components.

The unstrained co-ordinates x_1', x_2', x_3' of a point will not change as a direct result of a flow process;⁶ therefore in the present derivations these co-ordinates are considered independent of time. Differentiation of Equations [1] with respect to time gives the relations

$$\frac{\partial x_i''}{\partial t} = \sum_j \frac{da_{ij}}{dt} x_j', \quad (\text{for } i = 1, 2, 3) \dots [20]$$

The Eulerian velocity components along the x_1, x_2, x_3 co-ordinate directions are denoted by v_1, v_2, v_3 . The time rate of change of the displaced co-ordinates x_1'', x_2'', x_3'' of the particles of the body in the neighborhood on the reference point are therefore directly

$$\frac{\partial x_i''}{\partial t} = \sum_j x_j'' \frac{\partial v_i}{\partial x_j}, \quad (\text{for } i = 1, 2, 3) \dots [21]$$

In these Equations [21] the factors x_j'' in the terms of the right-hand side may be expressed in terms of x_j' by use of the relations, Equations [1]. The resulting right-hand sides of Equations [21] therefore become linear expressions in the x_j' and direct comparison of these coefficients with those in Equations [20] gives the expressions for the rates of change of the natural strain components due to flow. These expressions are

$$\frac{da_{ij}}{dt} = \sum_k a_{kj} \frac{\partial v_i}{\partial x_k}, \quad (\text{for } i, j = 1, 2, 3) \dots [22]$$

The principal strain ratios are given by Equations [19]. Their time derivatives are, accordingly, given by

$$\frac{d\alpha_i}{dt} = \sum_{j,k} \left(m_{ij} l_{ik} \frac{da_{jk}}{dt} + a_{jk} l_{ik} \frac{dm_{ij}}{dt} + a_{jk} m_{ij} \frac{dl_{ik}}{dt} \right), \quad (\text{for } i = 1, 2, 3) \dots [23]$$

The second and third terms in the summation of this equation vanish. This can be shown as follows: Sum the third terms with respect to j , and use Equations [9] to eliminate $a_{jk} m_{ij}$; the total contribution of this third term is thus seen to be

$$\sum_k \alpha_i l_{ik} \frac{dl_{ik}}{dt} = \frac{\alpha_i}{2} \frac{d}{dt} (\sum_k l_{ik}^2) = 0$$

⁶ The unstrained co-ordinates might be considered to change as an "indirect" result of a flow due to a relaxation phenomenon. For the present, however, only the direct results of flow are being considered. It will be seen later that this delicate question is sidestepped by use of the resolution into principal strains. In fact, this is the really fundamental reason for introducing this resolution.

Similarly, sum the second terms with respect to k and use Equations [17]; the contribution of this term is

$$\sum_j \alpha_i m_{ij} \frac{dm_{ij}}{dt} = \frac{\alpha_i}{2} \frac{d}{dt} (\sum_j m_{ij}^2) = 0$$

Thus only the first term in the summation on the right side of Equation [23] remains. Substitute Equations [22] into this first term and use Equations [17] to eliminate $a_{jk} l_{ik}$ factors; the resulting form of Equation [23] is

$$\frac{d\alpha_i}{dt} = \alpha_i \sum_{j,k} m_{ij} m_{ik} \frac{\partial v_j}{\partial x_k}, \quad (\text{for } i = 1, 2, 3) \dots [24]$$

It remains to determine the expressions for the rates of change of the direction cosines. These expressions will be derived only for the two-dimensional case in the next section.

(e) *Case of Two-Dimensional Flow and Strain.* The definition of two-dimensional strain in the x_1, x_2 -plane is that the deflection vector of all particles lies in the x_1, x_2 -plane, and all particles with the same x_1, x_2 -co-ordinates have the same deflection vector.

Referring to Equations [1], the condition on the natural strain components a_{ij} for two-dimensional strain in the x_1, x_2 -plane are

$$a_{13} = a_{31} = a_{23} = a_{32} = 0; \quad a_{33} = 1 \dots [25]$$

The corresponding two-dimensional flow is

$$\frac{\partial v_1}{\partial x_3} = \frac{\partial v_2}{\partial x_3} = v_3 = 0 \dots [26]$$

The relations for principal strains, principal strain directions, and rates of change of these due to flow are to be derived for this case of two-dimensional strain and flow.

The A_{ij} of Equations [11] for two-dimensional strain are

$$\left. \begin{aligned} A_{13} = A_{31} = A_{23} = A_{32} = 0; \quad A_{33} = 1 \\ A_{11} = a_{11}^2 + a_{12}^2 \\ A_{22} = a_{21}^2 + a_{22}^2 \\ A_{12} = A_{21} = a_{11}a_{21} + a_{12}a_{22} \end{aligned} \right\} \dots [27]$$

Thus Equations [15] for the direction cosines m_{ij} become

$$\left. \begin{aligned} (a_{11}^2 + a_{12}^2 - \lambda_i) m_{i1} + (a_{11}a_{21} + a_{12}a_{22}) m_{i2} &= 0 \\ (a_{11}a_{21} + a_{12}a_{22}) m_{i1} + (a_{21}^2 + a_{22}^2 - \lambda_i) m_{i2} &= 0 \\ (1 - \lambda_i) m_{i3} &= 0 \end{aligned} \right\} \dots [28]$$

The determinantal equation for λ_i is

$$(1 - \lambda_i)[\lambda_i^2 - (a_{11}^2 + a_{12}^2 + a_{21}^2 + a_{22}^2)\lambda_i + (a_{11}a_{22} - a_{12}a_{21})^2] = 0 \dots [29]$$

The root $\lambda_3 = 1$ is determined by the first factor in Equation [29]; substitution of this root into the first two of Equations [28] gives, with the help of Equations [4] and [4a]

$$m_{13} = m_{31} = m_{23} = m_{32} = 0; \quad m_{33} = 1 \dots [30]$$

With the values of Equations [30], the remaining direction cosines may be expressed as

$$m_{11} = m_{22} = \cos \theta; \quad m_{12} = -m_{21} = \sin \theta \dots [31]$$

where θ is the angle between the z_1 (principal) axis and the x_1 -axis. The meaning of Equations [30] is of course that the axes z_1 and z_2 lie in the x_1, x_2 -plane. The relative positions of these axes are shown in Fig. 1.

In order to determine the value of the angle θ , first determine the roots of the quadratic factor of Equation [29]. These roots are

$$\left. \begin{aligned} \lambda_1 &= \frac{1}{2} \left[(a_{11}^2 + a_{12}^2 + a_{21}^2 + a_{22}^2) \right. \\ &\quad \left. + \sqrt{(a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2)^2 + 4(a_{11}a_{21} + a_{12}a_{22})^2} \right] \\ \lambda_2 &= \frac{1}{2} \left[(a_{11}^2 + a_{12}^2 + a_{21}^2 + a_{22}^2) \right. \\ &\quad \left. - \sqrt{(a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2)^2 + 4(a_{11}a_{21} + a_{12}a_{22})^2} \right] \end{aligned} \right\} \quad [32]$$

Substitution of either of these values with Equations [31] into

FIG. 1 POSITION OF PRINCIPAL STRAIN AXES z_1, z_2 FOR TWO-DIMENSIONAL STRAIN IN x_1, x_2 -PLANE

either of the first two of Equations [28] will determine the angle θ . The result is most easily expressed as

$$\tan 2\theta = \frac{2(a_{11}a_{21} + a_{12}a_{22})}{a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2} \quad [33]$$

An expression for the rate of change of the angle θ is obtained by direct differentiation of Equation [33] with respect to time. This expression is

$$\begin{aligned} 2(\sec^2 2\theta) \times \frac{d\theta}{dt} &= \frac{2(a_{21} - a_{11} \tan 2\theta) da_{11}/(dt) + 2(a_{22} - a_{12} \tan 2\theta) da_{12}/(dt)}{a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2} \\ &\quad + \frac{2(a_{11} + a_{21} \tan 2\theta) da_{21}/(dt) + 2(a_{12} + a_{22} \tan 2\theta) da_{22}/(dt)}{a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2} \end{aligned} \quad [34]$$

Expressions [22] for the rate of change of the natural strain components due to flow become, for the two-dimensional case

$$\left. \begin{aligned} \frac{da_{11}}{dt} &= a_{11} \frac{\partial v_1}{\partial x_1} + a_{21} \frac{\partial v_1}{\partial x_2}, \quad \frac{da_{12}}{dt} = a_{12} \frac{\partial v_1}{\partial x_1} + a_{22} \frac{\partial v_1}{\partial x_2} \\ \frac{da_{21}}{dt} &= a_{11} \frac{\partial v_2}{\partial x_1} + a_{21} \frac{\partial v_2}{\partial x_2}, \quad \frac{da_{22}}{dt} = a_{12} \frac{\partial v_2}{\partial x_1} + a_{22} \frac{\partial v_2}{\partial x_2} \end{aligned} \right\} \quad [35]$$

Substitution of these relations into Equation [34] gives

$$\begin{aligned} 2(\sec^2 2\theta) \times \frac{d\theta}{dt} &= \left[\frac{-2(a_{11}^2 + a_{12}^2) \tan 2\theta}{a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2} + \tan 2\theta \right] \frac{\partial v_1}{\partial x_1} \\ &\quad + \left[\frac{2(a_{21}^2 + a_{22}^2)}{a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2} - \tan^2 2\theta \right] \frac{\partial v_1}{\partial x_2} \\ &\quad + \left[\frac{2(a_{11}^2 + a_{12}^2)}{a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2} + \tan^2 2\theta \right] \frac{\partial v_2}{\partial x_1} \\ &\quad + \left[\frac{2(a_{21}^2 + a_{22}^2) \tan 2\theta}{a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2} + \tan 2\theta \right] \frac{\partial v_2}{\partial x_2} \end{aligned} \quad [36]$$

The set of Equations [8] specialized for the two-dimensional case with the help of Equations [30] and [31] give

$$\left. \begin{aligned} a_{11} &= \alpha_1 l_{11} \cos \theta - \alpha_2 l_{21} \sin \theta \\ a_{12} &= \alpha_1 l_{12} \cos \theta - \alpha_2 l_{22} \sin \theta \\ a_{21} &= \alpha_1 l_{11} \sin \theta + \alpha_2 l_{21} \cos \theta \\ a_{22} &= \alpha_1 l_{12} \sin \theta + \alpha_2 l_{22} \cos \theta \end{aligned} \right\} \quad [37]$$

Further, reasoning similar to that used to derive Equations [31] shows that l_{11}, l_{12}, l_{21} , and l_{22} in the two-dimensional case may be expressed as

$$l_{11} = l_{22} = \cos \theta; \quad l_{12} = -l_{21} = \sin \theta \quad [38]$$

From Equations [37] and [38] the following relations may be obtained which are independent of the angle θ of Equations [38]

$$\left. \begin{aligned} a_{11}^2 + a_{12}^2 &= \alpha_1^2 \cos^2 \theta + \alpha_2^2 \sin^2 \theta \\ a_{21}^2 + a_{22}^2 &= \alpha_1^2 \sin^2 \theta + \alpha_2^2 \cos^2 \theta \end{aligned} \right\} \quad [39]$$

from which, finally

$$\left. \begin{aligned} \frac{2(a_{11}^2 + a_{12}^2)}{a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2} &= \frac{\alpha_1^2 + \alpha_2^2}{\alpha_1^2 - \alpha_2^2} \times \sec 2\theta + 1 \\ \frac{2(a_{21}^2 + a_{22}^2)}{a_{11}^2 + a_{12}^2 - a_{21}^2 - a_{22}^2} &= \frac{\alpha_1^2 + \alpha_2^2}{\alpha_1^2 - \alpha_2^2} \times \sec 2\theta - 1 \end{aligned} \right\} \quad [40]$$

Substitution of the relations, Equations [40], into [36] yields the final expression for the rate of change of the principal strain directions with flow in the two-dimensional case. This final expression is

$$\begin{aligned} 2 \frac{d\theta}{dt} &= \left(\frac{\alpha_1^2 + \alpha_2^2}{\alpha_1^2 - \alpha_2^2} \times \sin 2\theta \right) \left(\frac{\partial v_2}{\partial x_1} - \frac{\partial v_1}{\partial x_2} \right) \\ &\quad + \left(\frac{\alpha_1^2 + \alpha_2^2}{\alpha_1^2 - \alpha_2^2} \times \cos 2\theta \right) \left(\frac{\partial v_2}{\partial x_1} + \frac{\partial v_1}{\partial x_2} \right) + \left(\frac{\partial v_2}{\partial x_1} - \frac{\partial v_1}{\partial x_2} \right) \end{aligned} \quad [41]$$

The important characteristic of this expression is that it involves only the quantities $\alpha_1, \alpha_2, \theta$ which describe the "strained" condition at a point; quantities relating back to the unstrained condition, that is, the l_{ij} or angle θ_i of Equation [38], do not enter the expression at all. Thus the question of whether the unstrained condition at a point of a body is changing due, for example, to a relaxation process, has been sidestepped. Previous reference has been made to this result.⁵ In this connection it should also be noted that Equations [24] for the rate of change of the principal strain ratios is also independent of the quantities l_{ij} .

(f) *Case of Steady-State Simple Shear Flow.* A particularly simple and important case of two-dimensional strain and flow is the case of a steady-state simple shear flow. Steady flows of materials through tubes and channels are often of this character. The relations of the preceding subsection can be further specialized for this case.

The flow considered is a flow in the x_1 -direction for which

$$\frac{\partial v_1}{\partial x_2} = s = \text{const}; \quad v_2 = v_3 = \frac{\partial v_1}{\partial x_1} = 0 \quad [42]$$

A flow of this character results in two-dimensional strain in the x_1, x_2 -plane, for which $\alpha_3 = 1$. With Equations [31] and [42] the relations, Equations [24] for rate of change of the principal strain ratios become

$$\left. \begin{aligned} \frac{d\alpha_1}{dt} &= \alpha_1 s \sin \theta \cos \theta = \frac{1}{2} \alpha_1 s \sin 2\theta \\ \frac{d\alpha_2}{dt} &= -\alpha_2 s \sin \theta \cos \theta = -\frac{1}{2} \alpha_2 s \sin 2\theta \\ \frac{d\alpha_3}{dt} &= 0 \end{aligned} \right\} \quad [43]$$

For the rate of change of the principal strain directions, Equation [41] gives

$$\frac{d\theta}{dt} = \frac{s}{2} \left(\frac{\alpha_1^2 + \alpha_2^2}{\alpha_1^2 - \alpha_2^2} \cos 2\theta - 1 \right) \dots \dots \dots [44]$$

3 PHENOMENOLOGICAL DESCRIPTION OF LARGE-STRAIN ELASTICITY WITH STRESS RELAXATION

(a) *Axiomatic Basis of Description.* The phenomenological description of the stress-strain properties of materials, exhibiting large-strain elasticity with stress relaxation, is developed from the following axiomatic statements:

1 The state of stress is dependent solely upon the state of "elastic" strain.

2 The time rate of change of elastic strain is equal to the time rate of "geometric" strain plus a spontaneous time rate of change which depends only upon the current elastic strain, and corresponds to the relaxation process.

The second statement defines the new concept of elastic strain which the first requires. This axiomatic foundation can be restated at greater length, and in a manner which emphasizes the meanings of the terms elastic and geometric strain.

Geometric strain has been treated in Section 2; it specifies the relative movements of the individual particles of a material. The time rates of change of the principal (geometric) strain ratios due to flow of a material are given by Equations [24], and of the principal (geometric) strain directions, for the two-dimensional case, by Equation [41]. Elastic strain is specified in the same terms as geometric strain, but differs in that its time rate of change is equal to the rate of change of geometric strain plus an additional term which describes a spontaneous relaxation of elastic strain. Because of this additional relaxation term, elastic strain does not specify relative movements of the individual particles of a material, though it is related to the history of these movements in a definite way. It is asserted axiomatically that the state of stress in the material is a function only of the elastic strain thus defined, and that the relaxation rate of elastic strain depends only upon the elastic strain itself.

The distinction between geometric strain and elastic strain may be illustrated further by stating how each might, in theory at least, be observed. The state of geometric strain would be observed by marking a number of particles of the material and noting how their relative positions change. The state of elastic strain might be observed by cutting a small cubical element out of a material under flow or stress, and, removing it from its environment, allowing it immediately to assume its natural zero-stress shape. The geometric strain which would have to be imposed to bring the element back to its cubical shape and size when cut would be the elastic strain in the material under the flow or stress condition, or would be closely related to it.⁸

The materials treated will further be assumed to be incompressible, and to have a property of isotropy generalized for the case of large elastic strain. This generalized property of isotropy is defined as follows:

1 When a material is in an elastically unstrained state, its mechanical behavior is identical in all directions in the material.

2 When a material is in an elastically strained state, its mechanical behavior in any direction depends only upon the relation of this direction to the principal strain directions, and upon the principal elastic strains themselves.

It may be noted that the difference between this generalized isotropy and the classical isotropy is that isotropic behavior is not

⁸ This reservation is made for a reason which will be referred to in the sequel.

postulated for the superposition of one elastic strain upon another. The analytical difference between large and small strains is of this character; superposition of large strains does not follow a simple addition law, while superposition of small strains does.

A numerical determination of the stress corresponding to any specified deformation process in a material requires mathematical expressions for the spontaneous time rate of change of elastic strain due to the relaxation process, and a mathematical relation between the state of elastic strain and the state of stress. The formulation of these mathematical expressions is the principal aim of the theory.

(b) *Elastic Strain and Relaxation Relations.* In accordance with the method of specification of large strain developed in Section 2, the state of elastic strain may be specified by the three principal strain ratios $\alpha_1, \alpha_2, \alpha_3$, and the principal strain direction cosines m_i , or, in the two-dimensional case, the angle θ . Henceforth this notation will be used without alteration to specify elastic strain. Special mention will be made if geometric strain is referred to, and it is different from elastic strain.

The time rate of change of the principal elastic-strain ratios is given by

$$\frac{d\alpha_1}{dt} = \left(\frac{d\alpha_1}{dt} \right)_{\text{geom}} + \left(\frac{d\alpha_1}{dt} \right)_{\text{relax}} \dots \dots \dots [45]$$

with two similar equations for α_2 and α_3 . The terms $(d\alpha_i/dt)_{\text{geom}}$ are the rates of change of the elastic strain corresponding to change of geometric strain; in a flow these terms are given by Equation [24], in which α_i on the right side is the elastic-strain ratio. The terms $(d\alpha_i/dt)_{\text{relax}}$ describe the relaxation property of the material, and, as properties of the material, these terms must be characteristic functions of the elastic-strain state only. As a result of the assumed property of isotropy these terms must be functions only of the principal strain ratios $\alpha_1, \alpha_2, \alpha_3$, and are designated by R_1, R_2, R_3 ; thus

$$\left. \begin{aligned} \left(\frac{d\alpha_1}{dt} \right)_{\text{relax}} &= R_1(\alpha_1, \alpha_2, \alpha_3) \\ \left(\frac{d\alpha_2}{dt} \right)_{\text{relax}} &= R_2(\alpha_1, \alpha_2, \alpha_3) \\ \left(\frac{d\alpha_3}{dt} \right)_{\text{relax}} &= R_3(\alpha_1, \alpha_2, \alpha_3) \end{aligned} \right\} \dots \dots \dots [46]$$

A further consequence of the property of isotropy is that R_1, R_2, R_3 must be obtainable from each other by interchanging the variables $\alpha_1, \alpha_2, \alpha_3$; thus there is actually only a single relaxation function to be determined.

It is also a consequence of the property of isotropy that the directions of principal elastic strain are not changed by relaxation. Equation [41] is therefore valid for the change of elastic-strain direction in two dimensions provided that α_1 and α_2 on the right-hand side are elastic strains.

A set of geometric-strain ratios which correspond to zero volume change in a material must satisfy the relation

$$\alpha_1 \times \alpha_2 \times \alpha_3 = 1 \dots \dots \dots [47]$$

The rates of change of geometric strain for incompressible materials must therefore satisfy the relation obtained by setting the time derivative of the left side of Equation [47] to zero

$$\frac{1}{\alpha_1} \left(\frac{d\alpha_1}{dt} \right)_{\text{geom}} + \frac{1}{\alpha_2} \left(\frac{d\alpha_2}{dt} \right)_{\text{geom}} + \frac{1}{\alpha_3} \left(\frac{d\alpha_3}{dt} \right)_{\text{geom}} = 0 \dots [48]$$

However, there appears to be no fundamental reason that the

rates of change of elastic strain, $R_i = (d\alpha_i/dt)_{\text{relax}}$, must also satisfy Relation [48]. If they do not for a particular material, then, even though the material be incompressible, the Relation [47] need not hold for the elastic strain. This is actually the case for the simple molecular representation analyzed in Section 4, and is the reason for the reservation referred to previously.⁶

(c) *Stresses and Strain-Energy Function.* For rapidly applied geometric strain it is evident from Equation [45] that, since the terms $(d\alpha_i/dt)_{\text{relax}} = R_i$ are functions of $\alpha_1, \alpha_2, \alpha_3$, the relative effect of relaxation upon the elastic strain becomes small, and the resulting elastic strain is nearly equal to the applied geometric strain. In the limit of very rapidly applied geometric strain the elastic and geometric strains become identical. This fact has important theoretical consequences.

Together with the axiomatic assumption that the stress depends only upon elastic strain the possibility of coincidence of elastic and geometric strain establishes the existence of a strain-energy function ψ . This function is equal to the recoverable strain energy per unit volume stored up as a result of the action of the elastic stresses. As a result of the assumed property of isotropy, ψ depends only upon the principal elastic-strain ratios in such a way that its values are unaltered by any interchange of $\alpha_1, \alpha_2, \alpha_3$.

A further result of the possibility of coincidence of elastic and geometric strain is that the principle of virtual work can be used to obtain expressions for the stresses in terms of elastic strain from the strain-energy function. In such application of the principle of virtual work, elastic-strain increments are treated as geometric-strain increments.

It may be recalled that any stress condition at a point is equivalent to three principal tension (or compression) stresses, to be denoted by $\sigma_1, \sigma_2, \sigma_3$, acting across planes normal to the three principal stress directions. It is a consequence of the property of isotropy that the principal elastic-strain directions and the principal stress directions coincide. The zero stress condition $\sigma_1 = \sigma_2 = \sigma_3 = 0$ will be associated with the elastically unstrained condition $\alpha_1 = \alpha_2 = \alpha_3 = 1$.

The relation between stresses and strains can be derived from the strain-energy function by considering the virtual work done on an elemental volume of material during a small virtual deformation specified by elastic strain changes $\delta\alpha_1, \delta\alpha_2, \delta\alpha_3$. As remarked before, elastic-strain changes can be identified with geometric-strain changes for the purpose of applying the principle of virtual work.

Consider an element of material in the shape of a rectangular parallelepiped with sides normal to the principal strain directions. The lengths of the sides of the parallelepiped must remain proportional to the elastic-strain ratios in any virtual deformation, and can therefore be represented by $\alpha_1 L_1, \alpha_2 L_2, \alpha_3 L_3$, where L_1, L_2, L_3 are constant lengths.
